We propose a scheme that allows us to coherently extract cold atoms from a reservoir in a deterministic way. The transfer is achieved by means of radiation pulses coupling two atomic states which are object to different trapping conditions. A particular realization is proposed, where one state has zero magnetic moment and is confined by a dipole trap, whereas the other state with nonvanishing magnetic moment is confined by a steep microtrap potential. We show that in this setup a predetermined number of atoms can be transferred from a reservoir, a Bose-Einstein condensate, into the collective quantum state of the steep trap with high efficiency in the parameter regime of present experiments.

I. INTRODUCTION

Recent experimental progress with ultracold atomic gases has opened exciting directions in the study of many-body systems, aiming at the full coherent control of structures of increasing complexity [1]. Applications, like realizations of quantum information protocols, are very promising and presently investigated [1–6]. Moreover, these systems allow one to study the frontiers between the quantum and classical worlds [7].

In this perspective increasing interest has lately been attracted by the possibility of disposing single or a few cold atoms by deterministic extraction from a reservoir, thereby allowing one to control and manipulate them. This realization of tweezers applied to quantum objects has been called quantum tweezers. A recent proposal exploited tunneling from a condensate to a moving quantum dot in order to realize this scenario [8].

In this work we discuss an implementation of quantum tweezers, where trapping potentials, whose steepness depends on the atomic magnetic moment, are coupled by means of radiation. This procedure has been utilized for manipulating cold atomic clouds [9,10], and it has been proposed for engineering collective states of atoms in optical lattices [11]. Here, it is applied in order to coherently load atoms from a condensate into a steep trap by suitably coupling the atom electronic states. A sketch of the setup is shown in Fig. 1 and can be summarized as follows. Atoms are initially in a hyperfine state of zero magnetic moment, which we denote by \(|b\rangle\), where the atomic center of mass is confined by a dipole trap [12], and form a Bose-Einstein condensate (BEC). The state \(|b\rangle\) is coupled with radiation to the hyperfine state \(|a\rangle\), which has nonvanishing magnetic moment and is subject to the steep potential of a magnetic trap, like the ones implemented in [2,3,13–15]. The atoms are selectively transferred by means of radiative coupling between the condensate and a collective quantum state of the tweezers. The two traps can be found in the same spatial region and then coherently separated spatially after the transfer has occurred [10,16].

We investigate the dynamics and efficiency of quantum tweezers using radiation and show that their efficiency for transferring a certain number of atoms into the quantum state of a trap can be larger than 99% for experimentally accessible parameter regimes [17]. We study three implementations of atom transfer into the quantum tweezers: (i) by means of the adiabatic passage by adiabatically ramping the radiation frequency across the resonance [18], (ii) by combining adiabatic and diabatic passages by means of laser pulses [19], and (iii) by resonant coupling using pulses of well-defined area. The various techniques are compared and their efficiency is discussed in the parameter regime of experiments with microtraps [17].

This article is organized as follows. In Sec. II the theoretical model is introduced and the relevant parameters are
identified. In Sec. III the efficiency of the transfer for different realizations of the radiation coupling between the two hyperfine states is discussed. In Sec. IV the conclusions are drawn and outlooks are discussed. In the Appendices a detailed analysis of the parameter regime, where the quantum tweezers can be implemented, is presented.

II. THEORETICAL DESCRIPTION

We consider $N$ ultracold atoms of mass $M$ whose relevant internal degrees of freedom are the stable hyperfine states $|a\rangle$ and $|b\rangle$. The atomic center of mass experiences at position $x=(x,y,z)$ a harmonic potential $V_j(x)$ of the form

$$V_j(x) = \frac{1}{2} M (\nu_{jx}^2 x^2 + \nu_{jy}^2 y^2 + \nu_{jz}^2 z^2),$$

where $\nu_{jx}$, $\nu_{jy}$, and $\nu_{jz}$ are the frequencies along each Cartesian direction and $j=a,b$ labels the atomic state. The potential $V_j(x)$ is steeper than $V_h(x)$: namely, the frequencies $\nu_{ax}, \nu_{ay}, \nu_{az}$ of $V_h(x)$ are $\nu_{ax}, \nu_{ay}, \nu_{az}$ of $V_j(x)$. At time $t=0$ the atoms are all in the state $|b\rangle$ and constitute a Bose-Einstein condensate. The aim is to coherently transfer a predetermined number of atoms from the condensate, which acts as a reservoir, into a collective quantum state of the atoms in the steep potential $V_a(x)$.

Transfer of atoms into the quantum tweezers is implemented by suitably driving the states $|a\rangle$ and $|b\rangle$ with radiation pulses, which can be in the microwave or optical regime, thereby implementing a Raman transition. Coherent and selective transfer is achieved provided the radiation pulses are sufficiently short, so that incoherent dynamics during the interaction is negligible and sufficiently long to spectrally resolve a selected atomic transition. This latter statement will be quantified in Sec. II B. In the frame rotating at laser frequency, the relevant dynamics describing the interaction of the atom with radiation is given by the Hamiltonian $\mathcal{H}$, which we write as

$$\mathcal{H} = \mathcal{H}_a + \mathcal{H}_b + \mathcal{H}_{sc} + \mathcal{H}_{int}(t).$$

(2)

Here, the terms $\mathcal{H}_a$ and $\mathcal{H}_b$ describe the dynamics of the atom’s center of mass in the states $|a\rangle$ and $|b\rangle$, respectively, and have the form

$$\mathcal{H}_j = \int dx \psi_j^\dagger(x) \left[ -\frac{\hbar^2}{2M} \nabla^2 + V_j(x) \right] \psi_j(x) + \frac{1}{2} g_{jj} \int dx \psi_j^\dagger(x) \psi_j^\dagger(x) \psi_j(x) \psi_j(x),$$

where $\psi_j(x)$ [$\psi_j^\dagger(x)$] is the field operator annihilating [creating] an atom at position $x$ in the internal state $|j\rangle$, the term $g_{jj}=4\pi\hbar^2a_{jj}/M$ represents the interaction strength of two-body collisions of atoms in the state $|j\rangle$, and $a_{jj}$ denotes the $s$-wave scattering length ($j=a,b$). Collisions between atoms in different hyperfine states are described by the term

$$\mathcal{H}_{sc} = g_{ab} \int dx \psi_a^\dagger(x) \psi_b^\dagger(x) \psi_a(x) \psi_b(x),$$

(4)

where $g_{ab}=4\pi\hbar^2a_{ab}/M$ is the interaction strength, with the $s$-wave scattering length $a_{ab}$ for collisions between one atom in state $|a\rangle$ and one atom in state $|b\rangle$. The coupling with radiation is described by the time-dependent term

$$\mathcal{H}_{int}(t) = -\hbar \Delta(t) \int dx \psi_a^\dagger(x) \psi_a(x) + \frac{1}{2} \hbar \Omega_L(t) \int dx [\psi_b^\dagger(x) \psi_b(x) + H.c.],$$

(5)

where $\Omega_L(t)$ is the real-valued Rabi frequency and $\Delta(t)$ is the detuning of the radiation at time $t$ from the resonance frequency of the transition $|b\rangle \rightarrow |a\rangle$.

All atoms are initially in the internal state $|b\rangle$ and form a condensate. We denote this collective state, the ground state of $\mathcal{H}_b$ for $N$ atoms, by $|0\rangle$. By means of a radiation pulse a number $n$ of atoms (with $n<<N$) are transferred into the lowest-energy state of $\mathcal{H}_a$. We denote by $|n\rangle$ the state of the system after the transfer, corresponding to $N-n$ atoms in the ground state of $\mathcal{H}_b$ and $n$ atoms in the ground state of $\mathcal{H}_a$. The efficiency of the procedure is measured by the probability $P_{0\rightarrow n}(T)$, which corresponds to the probability at time $T$, at the end of the pulse, of finding $n$ atoms in the ground state of $\mathcal{H}_a$. It is defined as

$$P_{0\rightarrow n}(T) = |\langle n|U(T)|0\rangle|^2,$$

(6)

with

$$U(T) = T \exp \left( \frac{1}{\hbar} \int_0^T d\tau \mathcal{H}(\tau) \right)$$

(7)

and $T$ indicates the time ordering. In Sec. III we describe strategies of varying the coefficients $\Delta(t)$ and $\Omega_L(t)$ in $\mathcal{H}_{int}$ as a function of time in order to achieve unit efficiency.

A. Basic assumptions and approximations

In order to study the dynamics and the efficiency of the tweezers, we decompose the field operator in a convenient basis. Here, we use the Fock decomposition of the field operator $\psi_a(x)$: namely [20],

$$\psi_a(x) = \sum_{\alpha} \phi_a^\dagger(\alpha) a_{\alpha}^\dagger,$$

(8)

where $\alpha$ labels the excitations of the harmonic oscillator with Hamiltonian $\rho^2/2M + V_h(x)$, $\phi_a^\dagger(\alpha)$ is its wave function, and $a_{\alpha}$ is the field operator annihilating an atom in the corresponding state $|\alpha\rangle$. We remark that the state $|\alpha\rangle$ describes a single-particle eigenstate; hence, they are not the eigenstates of $\mathcal{H}_a$ when two or more (interacting) atoms are inside the tweezers. Nevertheless, in this case it still provides a plausible ansatz for estimating the order of magnitude of the physical parameters.

Since the number of atoms which are extracted from the condensate is negligibly small compared with $N$, we replace
the field operator for atoms in the hyperfine state \(|b\rangle\) by a scalar. At \(t=0\) the atoms are assumed to be in the condensate ground state with macroscopic wave function \(\phi_b(x)\) and chemical potential \(\mu\). These quantities are assumed to be constant and negligibly affected by the transfer of atoms into the tweezers. The condensate is hence a reservoir of atoms at given density \(n_b(x)=N|\phi_b(x)|^2\). The condensate excitations are accounted for by the (low-energy) collective modes at frequencies \(\omega_o\), and the part of Hamiltonian \(\mathcal{H}_b\) which may limit the efficiency of the quantum tweezers takes the form

\[
\mathcal{H}_b=\sum_j \omega_j p_j^a p_j^b.
\]

where \(p_j^a\) and \(p_j^b\) are the annihilation and creation operators of a phonon of energy \(\hbar \omega_i\). In addition, the quantum tweezers overlap spatially with the condensate, and collisions between the atom inside the tweezers and condensate, described by Eq. (4), can be detrimental for the coherence of the process. Their influence on the tweezers efficiency is discussed in Sec. II B. Below, we treat the Hamiltonian term (4) as a small perturbation, whose effect is to introduce small shifts of the energy levels.

In the situations we consider the condensate ground state is coupled (quasi)resonantly with the ground state of \(\mathcal{H}_a\) for \(n\) atoms and one or two atoms at a time are transferred into the steep potential. The states which are relevant to the dynamics are denoted by \(|0\rangle\), \(|1\rangle\), and \(|2\rangle\), corresponding to 0, 1, and 2 atoms in the quantum tweezers, respectively. Their energy is \(E(n)=\langle n|\mathcal{H}|n\rangle\) with \(n=0,1,2\). By setting \(E(0)=0\), they take the form

\[
E(n) = E_a(n) + E_w(n) - n\mu, \tag{9}
\]

where \(E_a(n)\) is the energy of \(n\) atoms in the ground state of the Hamiltonian \(\mathcal{H}_s\) and \(E_w(n)\) is the interaction energy due to the term (4), while the term \(-n\mu\) accounts for the extraction of \(n\) atoms from the condensate. The explicit expressions for \(E_a(n)\) and \(E_w(n)\) are found from the overlap integral between the condensate wave function and the wave function describing the ground state of \(\mathcal{H}_a\) for \(n\) atoms. We evaluate them by approximating the latter with the wave function of \(n\) noninteracting atoms in the ground state of the oscillator and find

\[
E_a(n) = n \left( \frac{1}{2} \sum_{j=x,y,z} \hbar \nu_{aj} - \hbar \Delta \right) + \Delta E_n \tag{10}
\]

and

\[
E_w(n) = g_{ab} n \int \text{d}x |\phi_a(x)|^2 |\phi_b(x)|^2. \tag{11}
\]

Here, we have denoted by \(\phi_b(x)\) the state \(\tilde{\phi}_a^n(x)\) with \(\tilde{n}_a=(0,0,0)\) and \(\Delta E_n\) is an energy shift due to particle-particle interactions in state \(|a\rangle\), which can be decomposed into the terms \(\Delta E_n = \Delta E_{\text{coll}} + \Delta E_{\text{dipole}}(t)\). The term \(\Delta E_{\text{coll}}\) accounts for the collisions of atoms in the ground state, which we estimate for \(n=2\) as

\[
\Delta E_{\text{coll}} = g_{aa} \int \text{d}x |\phi_a(x)|^4, \tag{12}
\]

while the term \(\Delta E_{\text{dipole}}(t)\) is due to dipole-dipole radiative interactions between the atoms inside the tweezers and it is proportional to the dissipative rate associated with the radiative transfer [21].

The coupling due to radiation between the states \(|n\rangle\) and \(|n+1\rangle\) is described by the matrix elements \(\langle n|\mathcal{H}|n+1\rangle = \langle n+1|\mathcal{H}|n\rangle\), with \(n=0,1\). We denote by

\[
\Omega_n^{(1)} = \frac{2}{\hbar} \langle n|\mathcal{H}|n+1\rangle \tag{13}
\]

the corresponding Rabi frequency, which takes the explicit form

\[
\Omega_n^{(1)} = \Omega_{1L} \sqrt{N(n+1)} \int \text{d}x \phi_a^\dagger(x) \phi_b(x). \tag{14}
\]

We assume that atoms are extracted from the center of the condensate, which here corresponds with the center of the tweezers. For a very steep tweezers trap, whose size is much smaller than the size of the condensate, the integral in Eq. (14) is approximated by

\[
\Omega_n^{(1)} = \Omega_{1L} n_b(n+1) \int \text{d}x \phi_a^\dagger(x), \tag{15}
\]

where \(n_b=n_b(0)\) is the density at the center of the condensate.

The resonant coupling between the states \(|0\rangle\) and \(|2\rangle\) can be characterized by the Rabi frequency

\[
\Omega_2^{(2)} = \frac{\Omega_1^{(1)} \Omega_1^{(1)*}}{E_2/2\hbar}, \tag{16}
\]

where the denominator corresponds to the value of the detuning for which the two states are resonantly coupled and

\[
E_2 = \sum_{j=x,y,z} \hbar \nu_{aj} + \Delta E_2 + E_{w}(2) - 2\mu. \tag{17}
\]

The coupling, Eq. (16), has been evaluated in the limit \(\Omega_1^{(1)} \ll E_2/\hbar\) in second-order perturbation theory [22].

For later convenience, we denote by \(\Delta = E_1/\hbar\) the detuning for which the states \(|0\rangle\) and \(|1\rangle\) are resonantly coupled, with

\[
E_1 = \frac{1}{2} \sum_{j=x,y,z} \hbar \nu_{aj} + E_{w}(1) - \mu. \tag{18}
\]

### B. Values of the parameters

In this section we estimate the order of magnitude of the energy terms and check the consistency of our assumptions for experiments where the tweezers trap is a magnetic microtrap. In particular, we consider a magnetic trap with spherical symmetry and an oscillation frequency of 30 kHz along each direction. Similar parameter regimes have been discussed in [17].

We first focus on the spectrum of one atom inside the tweezers. According to Eqs. (9) and (10), the energy of the vibrational ground state \(|1\rangle\) reads

\[
E(1) = E_a(1) + E_w(1) - \mu
\]

with
\begin{equation}
E_a(1) = \frac{3}{2} \hbar \nu_a - \hbar \Delta.
\end{equation}

For \( \nu_a = 2\pi \times 30 \text{ kHz} \) and \( \nu_b = 2\pi \times 100 \text{ Hz} \) and a condensate of \( N = 10^3 \) \(^{87}\text{Rb} \) atoms with density \( n_b \approx 3 \times 10^{13} \text{ atoms/cm}^3 \), one finds \( \mu / \hbar = 1.8 \text{ kHz} \) while \( E_a(1) / \hbar \) is orders of magnitude smaller. The ground state of two atoms inside the tweezers has energy \( E(2) = E_a(2) + E_{sc}(2) - 2\mu \) with

\begin{equation}
E_a(2) = 3\hbar \nu_a - 2\hbar \Delta + \Delta E_2,
\end{equation}

where \( E_{sc}(2) - 2E_{sc}(1) \). The term \( \Delta E_2 = \Delta E_{\text{coll}} + \Delta E_{\text{dipole}} \) describes the energy shift due to atom-atom interactions inside the tweezers. The term due to collisions is \( \Delta E_{\text{coll}} / \hbar = 2\pi \times 2 \text{ kHz} \). When the coupling between the hyperfine states is achieved with coherent Raman transitions and radiation in the optical range, the term due to dipole-dipole interaction is of the order of the excitation rate of the state \( |a \rangle \) and it is negligible for the considered setup. Hence, the frequency of the steep trap is the largest frequency scale, which determines also the size of the energy separation between the ground and first excited states of the two-atom tweezers.

From Eq. (10) it is visible that selective addressing of the states \( |1 \rangle \) and \( |2 \rangle \) requires one to resolve frequencies of the order of \( \Delta E_2 / \hbar \): namely, the interaction energy of the atoms inside the tweezers. This sets a fundamental limit on the parameters for implementing the transfer and, consequently, on the time for implementing the transition.

As in this parameter regime \( \Delta E_2 \gg E_{sc} \) it is justified to treat the Hamiltonian term \( \mathcal{H}_{sc} \), Eq. (4), as a small perturbation. Neglecting the coupling of the state \( |a \rangle \) with the excitations of the condensate is more delicate. This coupling can be neglected when the pulses spectrally resolve the condensate excitations. This assumption may be reasonable when the trap frequency \( \nu_b > 2\pi \times 1 \text{ kHz} \). In this work we will neglect this coupling, although in general its effect must be taken into account for smaller values of \( \nu_b \). Its systematic study in such regime will be object of future investigations.

We discuss now the approximation on the ground-state wave function of \( |n \rangle \). It is in fact questionable whether one can approximate the wave function of the state \( |n \rangle \), with \( n \gg 2 \), with the product of single-particle wave functions. We note, however, that the size of the ground-state wave function in the steep trap we consider here is still larger than the s-wave scattering length. Numerical studies have shown that two-body s-wave scattering is still a reasonable approximation in relatively steep traps [23–25]. Hence, although the ansatz we use is not reliable for exact results, it is still plausible for gaining insight into the efficiency of the tweezers. Nevertheless, it is understood that the application of the schemes discussed below to a certain experiment requires accurate knowledge of the relevant parameters, which have to be evaluated for the specific atomic species and trapping conditions.

III. TWEEZING ATOMS WITH LASERS

In this section we discuss three methods of shaping radiation pulses in order to transfer a definite number of atoms from the condensate into the microtrap. The first method uses adiabatic ramping of the frequency of the radiation coupling \( |n-1 \rangle \rightarrow |n \rangle \) (adiabatic passage) [11,18]. The second method is based on the combination of two pulses, which induce a sequence of adiabatic and diabatic passages [26]. The third method uses resonant pulses with well defined pulse area [18].

A. Adiabatic passage

We consider the transfer of \( n \) atoms from the condensate into the quantum tweezers by adiabatically ramping the frequency of radiation coupling the two atomic states. The frequency of the pulse—namely, the detuning \( \Delta(t) \) in Eq. (5)—is slowly varied as a function of time from the initial value \( \Delta_i \) to the final detuning \( \Delta_f \), allowing the system to follow adiabatically the evolution.

Figure 2 displays the energy eigenvalues of \( \mathcal{H} \) as a function of the detuning \( \Delta \). Adiabatically sweeping the detuning through these resonances corresponds to remaining in an instantaneous eigenstate of the Hamiltonian \( \mathcal{H} \). Transfer of one atom is implemented by ramping the detuning between the values \( \Delta_i \) and \( \Delta_f \) in Fig. 2, corresponding to change the en-
The transfer of two atoms into the tweezers can be achieved starting from the state $|0\rangle$ by adiabatically ramping the detuning $\Delta$ either (i) subsequently across the resonances $E(0)=E(1)$ and then $E(1)=E(2)$ (lower dashed line in Fig. 2) or (ii) across the resonance $E(0)=E(2)$. The first case corresponds to transferring one atom at a time. In the second case, two atoms are transferred simultaneously. This latter implementation has a drawback due to the small value of the radiative coupling between the states $|0\rangle$ and $|2\rangle$. In fact, the corresponding Rabi frequency, estimated in Eq. (16), is in general rather smaller than the Rabi frequency $\Omega_1^{(1)}$, Eq. (14), describing the transfer of one atom into the tweezers. This smaller value leads to smaller energy splitting at the avoided crossing between the levels $|0\rangle$ and $|2\rangle$, therefore imposing much stricter limits on the ramping speed. The lower quadrants of Fig. 3 depict the results of the simulation for the sequential adiabatic transfer of two atoms into the microtrap. The efficiencies and transfer times are comparable with the efficiencies reached for transferring a single atom, showing that two atoms can be transferred into the ground state of a tweezers trap with $v_r=2\pi \times 30$ kHz in few milliseconds. The dashed curve corresponds to the Landau-Zener prediction, which in the adiabatic region is to good approximation the product of the transfer probabilities at the single avoided crossings, and takes the form $P_{0\rightarrow 2}^{(LZ)}=P_{0\rightarrow 1}^{(LZ)} P_{1\rightarrow 2}^{(LZ)}$. Here $P_{1\rightarrow 2}$ is found from Eq. (22), where the energy splitting $\delta$ is $\hbar |\Omega_2^{(1)}|$. 

B. Adiabatic passage using pulses

We discuss now the transfer of atoms into the tweezers by means of the so-called Stark-chirped rapid adiabatic passage (SCRAP) technique [26]. Here, population transfer between two quantum states is achieved by suitably varying the Rabi frequency $\Omega_s(t)$ and the detuning $\Delta(t)$ in Eq. (5), thereby combining adiabatic and diabatic transitions. In this scheme, two pulses of finite duration are utilized, which are a time-delayed one with respect to the other. One pulse is far-off resonance and induces an ac Stark shift $\Delta(t)$ on the transition $|b\rangle \rightarrow |a\rangle$, while the second pulse, which we denote by “pump pulse,” couples (quasi)resonantly the states $|a\rangle$ and $|b\rangle$ and has Rabi frequency $\Omega_s(t)$. The detuning is shaped in order to fulfill the resonance condition $\Delta(t)=E_s/\hbar$ at two instants of time $t_1$ and $t_2$. The shaping and time delay between the two pulses is such that at $t_1$ the system undergoes an adiabatic passage of the same type as the one discussed in Sec. III A, while at $t_2$ the transition is diabatic, thereby ensuring that at the end of the pulses the transfer between the states $|0\rangle$ and $|1\rangle$ is achieved. A possible realization of the pulses as a function of time and the corresponding dynamics are displayed in Fig. 4. Here, the energy levels $E(0)$ and $E(1)$ cross at the instant $t_1=0$ and $t_2=\tau$. At these instants, the system undergoes an adiabatic and diabatic transition, respectively. As a result, if initially all atoms are in the condensate, then

\[ P_{0\rightarrow 1}^{(LZ)} = 1 - e^{-\alpha_{ad}}, \]

with $\alpha_{ad}=\pi \delta^2/2 \hbar^2 |\Delta(t_0)|$ the adiabaticity parameter and $\Delta(t_0)$ and $\delta$ the rate of ramping and the energy splitting, respectively, at the avoided crossing between $E(0)$ and $E(1)$. Efficiencies of the order of 99% are achieved for transfer times of the order of milliseconds. The results show that faster transfer is achieved at larger trap frequencies. In fact, the interaction energy $\Delta E_2$ increases with $v_r$, thereby allowing for larger values of the ramping rate according to Eq. (21).

\[ |\Delta(t_0)| \ll \frac{\pi (\Delta E_2/\hbar)^2}{2 |\ln(1 - P_0)|}, \]
finally one atom is transferred into the ground state of the tweezers.

Since at least at one avoided crossing the dynamics must be adiabatic, the bounds on the values of the Rabi frequency and on the time variation of the ac Stark shift are basically the same as for the adiabatic passage in Sec. III A. Moreover, the finite size of the pulses and the requirement that a diabatic transition take place at one of the crossings introduces a further parameter—namely, the width of the pump pulse $T_V$, on which the transfer efficiency depends. The parameter regime for the applicability of this technique is discussed in detail in Appendix B.

Figure 5(a) displays the transfer efficiency as a function of $T_V$ and $\hat{\Omega}$, the maximum Rabi frequency of the pump pulse, as obtained from a numerical simulation for a tweezers trap with $\nu_p=2\pi \times 30$ kHz. Transfer efficiencies $P_{0\rightarrow 1} > 99\%$ are achieved in the white region, corresponding to transfer times of the order of some milliseconds. High efficiencies are reached for a relatively wide range of parameters, showing that the method is robust to fluctuations of the parameters of the pulses. These data have been evaluated under the condition for which the pump pulse achieves its maximum value at the same instant of time at which the detuning pulse fulfills the resonance condition, as depicted in Fig. 4. In this case the ideal conditions for adiabaticity are reached. The effect of a time lag $\delta \tau$ between these two events is shown in Fig. 5(b), which reports the dependence of the transfer efficiency on $\delta \tau$. The transfer efficiency exhibits a wide plateau around $\delta \tau=0$, which is of the order of a millisecond, showing that the method is also very robust against this kind of fluctuations. Note that the curve exhibits a second maximum at $\delta \tau \approx -4$ ms, corresponding to the case in which the pump pulse is centered at the second instant $t_2$ at which $\Delta$ fulfills the resonance condition $\Delta=E_1/\hbar$; namely, to the situation in which the sequence of adiabatic and diabatic passages is reversed. Ideally, the two maxima should be symmetric. Asymmetry here arises from the fact that the dynamics at the crossing corresponding to the resonance for simultaneous transfer of two atoms into the tweezers [dashed vertical line in Fig. 4(b)] is not perfectly diabatic. This intro-
FIG. 6. (Color online) Sketch of the dynamics when implementing the SCRAP technique for transferring sequentially two atoms into the tweezers. (a) Pump pulse [\(\Omega_L(t)\)] and ac Stark shift [\(\Delta_1(t)\)] as a function of time. (b) Corresponding spectrum. The lines in (b) are the energies \(E(n,l)\) as evaluated at the corresponding value of \(\Delta_1(t)\). The dashed curves indicate the dressed-state energies. The vertical lines indicate the instants at which the transition \([0] \rightarrow [1]\) and \([1] \rightarrow [2]\) are driven resonantly. Transfer of two atoms is achieved when the dynamics start at the blue solid curve.

Simultaneously, a fundamental difference in the efficiency of transfer, which depends on whether this transition point is crossed: namely, on whether the diabatic transitions occur before the adiabatic one.

Similarly to the adiabatic passage in Sec. III A, transfer of two atoms by means of SCRAP is better implemented sequentially—i.e., by transferring one atom at a time. Figure 6 shows a pulse sequence and the corresponding energy spectrum as a function of time for transferring sequentially two atoms inside the tweezers. The ideal dynamics follow the lower dashed line in Fig. 6(b). The transfer efficiency as a function of \(T_\Omega\) and \(\Omega\) is displayed in Fig. 7. Here, efficient transfer of two atoms, larger than 99%, is achieved in times of the order of several milliseconds. The relatively broad range of values for which \(P_{0\rightarrow 2}\) exceeds 99% shows that the method is robust against parameter fluctuations.

C. Transfer by population inversion

We finally discuss transfer of atoms into the tweezers by radiation pulses of chosen areas, coupling resonantly the states \([0]\) and \([1]\). Perfect transfer is achieved when \(\Delta = E_1/h\) and when the pulse area fulfills the relation \(\int d\tau \Omega_1^{(1)}(\tau) = \pi\). The limitations are on the choice of the Rabi frequency, whose value is bound by the interaction energy in order to have negligible coupling to off-resonant states (see Appendix A), and on the pulse duration, which must be sufficiently long to guarantee the spectral resolution of the tweezer energy levels. In Fig. 8 the transfer efficiency \(P_{0\rightarrow 1}\) is plotted for Gaussian pulses as a function of the pulse maximum intensity and duration. Efficiencies close to unity are realized with pulses of millisecond duration.

Efficient transfer of two atoms is achieved by sequentially sending two pulses, each transferring one atom into the tweezers. Here, the first pulse is resonant with the transition \([0] \rightarrow [1]\), thereby implementing a \(\pi\) rotation. A \(\pi\) rotation on the transition \([1] \rightarrow [2]\) is achieved by coupling it with a second pulse with detuning \(\Delta = (E_2 - E_1)/h\) and suitable pulse area. The spectral resolution, at the level of \(\Delta E_2/h\), avoids that during the second pulse the atom in the tweezers is transferred back to the condensate, as the transition \([0] \rightarrow [1]\) is far-off resonance. Transfer efficiencies exceeding 99% are achieved on time scales of the order of several milliseconds.

IV. DISCUSSION AND CONCLUSIONS

We have investigated the feasibility of a scheme that employs radiation, thereby achieving the deterministic extraction of atoms from a Bose-Einstein condensate and their transfer into the quantum state of a steep trap. We have shown that a high transfer efficiency can be achieved in times of the order of some milliseconds in parameter regimes which are within reach of present experiments with microtraps [17]. The radiation used for implementing the extraction can be either in the microwave regime, thus coupling directly, say, a magnetic dipole transition like in [9,10], or in
the optical domain, thereby implementing Raman transitions. Their application depends on the specific details of the system.

The results presented here refer to ideal conditions, where at \( t=0 \) all atoms are in the condensate ground state and the coupling with the other excited states of the condensate can be neglected. The presence of noncondensed atoms and the coupling of the state \( |a\rangle \) to the condensate excitations have not been considered. The presence of noncondensed atoms introduces a source of noise into the process, giving an indetermination in the transfer efficiency of the order of the noncondensed fraction. The coupling of the state \( |a\rangle \) to the condensate excitations constitutes a further source of noise which limits the efficiency of the tweezers. Its effect can be eliminated by resolving spectrally the condensate excitations. This is possible when the condensate is confined in a sufficiently steep trap. In this case, the condensate excitations must be taken into account when setting the parameters, as they determine the spectral resolution to be achieved and eventually the transfer duration.

Our analysis has been restricted to the transfer of one and two atoms into the corresponding tweezers ground state. Similar considerations apply for the transfer into one- and two-atom excited states. In this case, the parameters must be carefully set, so to spectrally resolve the desired level. The process, in this case, may take advantage of symmetries, ruling out the coupling to states which may be close but orthogonal to the initial state. The procedure discussed in this paper can be as well extended to the transfer of three or more atoms into the tweezers. In this case, we expect that the scheme is efficient when transferring sequentially one atom at a time. When confining three or more atoms into the steep trap, however, one must consider many-body effects which can give rise to instabilities. The dynamics and time scales on which they manifest themselves depend on the trap parameters and atomic species and have to be analyzed case by case.

To conclude, the possibility of extracting atoms on demand from a condensate realizes the deterministic coupling of an atom trap to a reservoir, thereby finding several analogies in quantum optical systems, and opens interesting perspectives in the study and control of coherent matter waves.

APPENDIX A: LIMITS FOR THE APPLICATION OF THE ADIABATIC PASSAGE

In this appendix we discuss the parameter regimes for which the dynamics described in Sec. III A apply. We first summarize the dynamics of the adiabatic passage by discussing the transfer of one atom into the tweezers. The considerations made here can be directly extended to the transfer of \( n \) atoms. We assume that the detuning is swept between the initial value \( \Delta_i \) and the final value \( \Delta_f \) in the interval of time \( T \), such that \( \Delta(0)=\Delta_i \) and \( \Delta(T)=\Delta_f \). Efficient transfer from \( |0\rangle \) to \( |1\rangle \) is achieved when at these values of the detuning the states \( |0\rangle , |1\rangle \) are eigenstates of \( \hat{H} \) to good approximation. The value of the Rabi frequency is bound from the constraint that the relevant dynamics must involve only the states \( |0\rangle \) and \( |1\rangle \). When these conditions are fulfilled, the dynamics
can be restricted to the subspace of states \(\{|0\}, |1\rangle\) and the eigenvalues of the reduced Hamiltonian at a given instant \(t\), \(0 \leq t \leq T\), are

\[
\epsilon_d(t, t) = \frac{1}{2} \Delta_1(t) + \frac{1}{2} h \Delta_1(t)^2 + |\Omega_1^{(1)}|^2,
\]

with

\[
\Delta_1(t) = \Delta(t) - E_J/h.
\]

We now identify the parameter regime for which one may restrict the dynamics to the levels \(|0\rangle\) and \(|1\rangle\). This approximation is justified when (i) coupling to single-particle excitations of the one-atom tweezers is negligible—i.e., \(|\Omega_1^{(1)}| \ll \nu_1\)—and (ii) when the state \(|2\rangle\) contributes negligibly to the dynamics—namely, when the condition

\[
|\Omega_1^{(1)}| \ll \Delta E_J/h
\]

is fulfilled. This condition on \(\Omega_1^{(1)}\) ensures also a complete adiabatic transfer by ramping the detuning across the resonance \(E(0)=E(1)\) while keeping \(\Omega_1\) constant. In fact, in this limit the final detuning \(\Delta_f\) can be chosen sufficiently far away from the resonance \(E_J/2h\) and at the same time be sufficiently large so that at \(\Delta_f\) the unperturbed states \(|0\rangle\) and \(|1\rangle\) are to good approximation eigenstates of \(H\).

We now evaluate the probability \(P_{0\rightarrow 1}\) of transferring one atom into the ground state of the tweezers when the dynamics can be restricted to the levels \(|0\rangle\) and \(|1\rangle\). In the adiabatic regime the probability \(P_{0\rightarrow 1}\) can be evaluated by using the Landau-Zener formula, which at the asymptotics—i.e., for large transfer efficiencies—takes the form

\[
P_{(LZ)}(0\rightarrow 1) = 1 - e^{-\alpha_{ad}}.
\]

Here \(\alpha_{ad}\) is the adiabaticity parameter, defined as

\[
\alpha_{ad} = \frac{\pi \delta^2}{4h^2 |\Delta(t)|^2}.
\]

The parameter \(\alpha_{ad}\) is proportional to the energy splitting \(\delta\), defined in Eq. (A5), and is inversely proportional to the time derivative of the detuning \(\Delta\) at the level crossing. Hence, the probability \(P_{(LZ)}^{(0\rightarrow 1)}\) approaches unity for large values of \(\alpha_{ad}\)—i.e., for large values of the energy splitting and/or small values of the rate \(\Delta\).

We fix now the threshold value \(P_0\), such that for \(P_{0-1} \geq P_0\) the transfer is considered successful, and we evaluate the rate \(\dot{\Delta}\), and thus the minimum time, required for transferring successfully one atom into the tweezers. From Eq. (22) we find that \(P_{0-1}^{(LZ)} \geq P_0\) when

\[
|\Delta(t)| \leq \frac{\pi (\delta h)^2}{2 |\ln(1 - P_0)|}.
\]

Using Eqs. (A5) and (A6) we rewrite this condition as

\[
|\Delta(t)| \leq \frac{\pi (\Delta E_J/h)^2}{2 |\ln(1 - P_0)|}.
\]

Hence, the time \(t_1\) needed for transferring one atom into the tweezers must fulfill the relation

\[
\tau_1 = \left| \frac{\Delta_f - \Delta_i}{\Delta(t_0)} \right| \geq \frac{2}{\pi} \frac{|\ln(1 - P_0)|}{\Delta E_J/h},
\]

where we have taken \(|\Delta_f - \Delta_i| \sim \Delta E_J/h\). With the parameters of Sec. II B, for \(\Delta E_J/h=2 \pi \times 2\ kHz\) and a success probability \(P_0=99\%\), the transfer time must fulfill the relation \(\tau_1 \geq 0.2\ ms\).

**APPENDIX B: LIMITS FOR THE APPLICATION OF SCRAP**

In this appendix we discuss the parameter regimes for which the dynamics described in Sec. III B applies. For simplicity we consider the case in which both the pump and the far-off-resonance pulse have Gaussian envelope and are given by

\[
\Omega_\lambda(t) = \hat{\Omega} \exp\left[-\frac{\tau^2}{T_\lambda^2}\right],
\]

and

\[
\Delta(t) = \Delta_{off} + \hat{\Delta} \exp\left[-\frac{(t-t_f)^2}{T_\Delta^2}\right],
\]

where \(T_\lambda\) and \(T_\Delta\) are the pulse widths, and the terms \(\hat{\Omega}\) and \(\hat{\Delta}\) denote the pulse maxima, and the offset value \(\Delta_{off}\) is such that at the instants \(t_1\) and \(t_2\) the resonance conditions \(\Delta(t_1)=\Delta(t_2)=E_J/h\) are fulfilled. Here, we have chosen \(t_1 \leq t_2\), so that the adiabatic passage occurs at the first crossing, and set \(t_1=0\) and \(t_2=\tau\).

The system dynamics can be reduced to the two levels \(|0\rangle\) and \(|1\rangle\) provided that the relation in Eq. (A6) is fulfilled, which sets an upper bound to the maximum value \(\hat{\Omega}\) that the pump pulse reaches. The dynamics is adiabatic around the point \(t_f\) provided that the pulses time variation is sufficiently smooth such that the adiabaticity parameter in Eq. (A8) is very large. For this reason, ideally the pump pulse should reach its maximum at \(t_1\), such that the level splitting is maximum at the avoided crossing. The adiabaticity of the transfer at \(t_1\) can be evaluated by checking for which parameters the adiabaticity parameter \(\alpha_{ad}\) of Eq. (A8) is much larger than unity. From Eqs. (A6) and (A8) one finds a condition for the
temporal variation of the detuning. For Gaussian pulses as in Eq. (B1b) this condition takes the form

$$\frac{\pi \Delta E_2^2}{4 \hbar^2} \gg \frac{\Delta \tau}{\tau_\Delta} \exp \left( - \frac{\tau^2}{\tau_\Delta^2} \right), \quad (B2)$$

where here \( t_1 = 0 \).

Ideally, the adiabatic transition between two eigenstates of \( \mathcal{H}_a + \mathcal{H}_b \)—say, \( |0\rangle \) to the state \( |1\rangle \)—is implemented over an infinite time. As the pump pulse has a finite duration \( T_\Omega \), then \( T_\Omega \) must exceed a minimum value \( t_{\text{pump}} \) in order to achieve sufficiently large transition probabilities at the instant \( t_1 \). Using the relation \( t_{\text{pump}} \sim 2 \Omega_1 / |\Delta(t_1)| \) [30], where \( \Omega_1 \) is the largest value of the coupling between \( |0\rangle \) and \( |1\rangle \), this condition corresponds to

$$T_\Omega \gg \Omega_1^2 T^2 \exp \left( \frac{\tau^2}{\tau_\Delta^2} \right), \quad (B3)$$

which fixes a relation between the widths and maxima of the two pulses and their relative delay. Simple algebra shows that this condition is consistent with the condition in Eq. (B2) provided that \( \Delta E^2 T_\Omega / \hbar \gg 1 \).

Finally, the transition is diabatic at \( t_2 = \tau \) when the pump pulse is very small at this instant—i.e., \( T_{\Delta} > T_\Omega \) and, more specifically, \( \tau > T_0 \). A condition for diabaticity is derivable imposing that the adiabaticity parameter at \( t_2 \) be \( \alpha_{\text{ad}}(t_2) \ll 1 \), thereby finding a bound on the time lag \( \tau = t_2 - t_1 \) which also depends on the form of the pulse envelopes.
