## Abstract

While climatic extremes are predicted to increase with global warming, we know little about the effect of climatic variability on biome distribution. Here, we show that rainy El Niño Southern Oscillation (ENSO) events can enhance tree recruitment in the arid and semiarid ecosystems of north-central Chile and northwest Peru. Tree-ring studies in natural populations revealed that rainy El Niño episodes have triggered forest regeneration in Peru. Field experiments indicate that tree seedling recruitment in Chile is much less successful than in Peru due mostly to larger mortality caused by herbivores. The dramatic impact of herbivores in Chile was derived from the combined result of slower plant growth and the presence of exotic herbivores (European rabbits and hares). The interplay of herbivory and climatic effects we demonstrated implies that rainy ENSO events may represent ‘windows of opportunity’ for forest recovery if herbivore pressure is minimized at the right moment.

## Introduction

Arid and semiarid ecosystems occupy 40% of the Earth’s land surface (Millennium Ecosystem Assessment, 2005) and are among the systems predicted to be most sensitive to future changes in climate (IPCC, 2001). As climatic extremes are expected to become more frequent, understanding how these ecosystems respond to present climatic fluctuations can improve our predictions on how they may change in the future. The El Niño Southern Oscillation (ENSO) cycle is the most prominent source of interannual climatic variation on our planet and affects large area of drylands worldwide (Allan *et al.*, 1996). El Niño-like conditions have become more frequent in the last decades (Trenberth & Hoar, 1997; Tudhope *et al.*, 2001), and although there are

considerable uncertainties in the prediction of such future events (Collins, 2000; Cobb *et al.*, 2003), ENSO events could increase in magnitude and frequency as result of global climate warming (Timmermann *et al.*, 1999).

During an El Niño phase, there is a shift in the rainfall convective zone towards the eastern Pacific produced by interconnected changes in atmospheric pressure, the strength of the trade winds, and ocean circulation. As a result, drought conditions affect large portions of Australia, Indonesia and the Philippines, while torrential rains can occur in the island states of the central Pacific and along the west coast of South America. This shift in the rainfall convective zone also leads to changes in atmospheric circulation (known as teleconnections) that propagate the influence of El Niño around the planet. As a consequence, during an El Niño episode, rainfall dramatically increases in certain areas of the world, while severe droughts occur in other regions. The El

Niño phase lasts approximately 1 year before the climatic conditions often reverse in a La Niña phase. The oscillation between El Niño and La Niña is irregular, but typically occurs once every 3–6 years (Allan *et al.*, 1996; McPhaden, 2004).

As water availability is a limiting factor in arid and semiarid ecosystems, rainy ENSO years trigger an extraordinary response in plant productivity that cascades across trophic levels (Holmgren *et al.*, 2001, 2006). Particularly important are the effects of these large rainfall pulses on the recruitment of trees and shrubs because woody cover expansion can have significant impacts on water and nutrient cycles, diversity of plants and animals and land use activities. Observations from Australia (Austin & Williams, 1988), the southeastern USA (Brown *et al.*, 1997), and northwest Peru (Vilela, 2002) suggest that extreme rainy ENSO events may trigger long lasting shifts in semiarid vegetation by facilitating the establishment of trees and shrubs. Effects of these rainy pulses, however, appear to differ widely between regions. For instance, in contrast to the Peruvian situation, long-term observations in north-central Chile show hardly any change in shrub cover after rainy ENSO events (Gutiérrez *et al.*, 1997). It is likely that differences in woody cover regeneration during ENSO events are partly modulated by herbivore pressure (Holmgren & Scheffer, 2001). Indeed synchronized reduction in herbivory during these rainy pulses has been key to explain woody regeneration in Australia (Austin & Williams, 1988) and the Sonoran Desert (Bowers, 1997).

In this paper, we show correlations between tree recruitment and rainy ENSO events in north-central Chile and northwest Peru, and present evidence for the idea that the differences in response between these regions may be explained by variations in herbivory pressure and plant growth rate. Our analysis is based on a combination of tree-ring studies and controlled field experiments.

## Materials and methods

### Study species

We studied one native tree species from Peru (*Prosopis pallida* H.B.K.) and one from Chile (*Prosopis chilensis* Mol Stuntz) both belonging to a genus that is widely distributed in South America (Pasiiecznik, 2001). *P. pallida* is a dominant species in the dry forests of north Peru and highly valuable for the local rural economies. *P. chilensis* used to have a wide distribution from the hyperarid to semiarid zones in Chile (Arce & Balboa, 1989) before indiscriminated logging and grazing reduced it to a species in vulnerable state with only scatter adult

individuals (Squeo *et al.*, 2001). Both tree species are considered priority targets for local reforestation programs (Arce & Balboa, 1989; Vilela, 2002).

### Study sites

*Fray Jorge (north-central Chile)*. The experimental site was located next to the Fray Jorge Forest National Park, 85 km south of La Serena and 25 km from the highway (30°41'S, 71°37'W) on a south-east faced gentle slope (10°; 200 m a.s.l.), within a private farm (Fundo El Salitre). This old-field site is currently being used for livestock grazing.

The climate is semiarid Mediterranean with the precipitation concentrated in the winter months (May–September); summer months are warm and dry. Mean annual precipitation is  $145.4 \pm 31.3$  mm (1 SE; 1989–2002, Weather Station at Fray Jorge). Longer meteorological records from La Serena (60 km north) report an average of 114.4 mm (1878–1998, Soto & Ulloa, 1997). High-rainfall events are associated with the ENSO phenomenon (Aceituno & Montecinos, 1992). In rainy El Niño years, annual precipitation averages 174 mm (years 1875–2000), with occasional strong events over 200 mm (e.g. in 1997, 233.4 mm, 1905, 487 mm which is the strongest recorded event). In contrast to the top ridges of the coastal mountain range, fog is not an important source of water availability in lowlands such as our study site (Squeo *et al.*, 2006). Mean annual temperature is 13.6 °C (1998–2003), January is the warmest month (ca. 17 °C) and July is the coldest one (ca. 10 °C; López-Cortés & López, 2004). Annual potential evapotranspiration reaches 1000 mm.

*Piura (northwest Peru)*. The experimental site was located within the University of Piura campus (5°10'S, 80°37'W; 30 m a.s.l.). Rainfall is concentrated in the summer months (December–May) and strongly influenced by ENSO events (Ortlieb, 2000). Although mean annual precipitation is 50 mm (1961–1983; Bernex de Falen & Reves, 1988), it is highly variable (e.g. ranging from 2.8 mm in 1996 to 1639 mm in 1998). Mean annual temperature is 24 °C, being warmest in February (27.9 °C) and coolest in August (21.1 °C). Annual potential evapotranspiration reaches 1825 mm.

### Dendrochronological studies

In January 2002, we took a total of 228 *P. pallida* wood samples from seven different locations around Piura, north Peru. In January 2003, we took 190 samples from *P. chilensis* trees from seven locations of the Coquimbo Region, north-central Chile. In both countries, we

sampled only natural populations that had clearly not been under irrigation. In Peru, tree samples consisted of tree disks from recently cut trees, which are abundantly found in the region. In Chile, we took one tree core per tree at the base of the trunk using a special borer for hard wood (HD-borer 300 mm Patience & Nicholson, Aust. Pty Ltd, Kaipoi, New Zealand) connected to a gas powered drill (Tanaka TED262R, Tanaka Kogyo Co. Ltd, Narashino-shi, Chiba, Japan).

Samples from Peru and Chile were first rough polished with a belt sander, and then with a sheet sander with sand paper of up to 1000 grit. Samples were observed under a binocular microscope and growth rings were marked with a very finely sharpened pencil. Samples were then scanned at a resolution of 0.015875 mm using an Epson Expression 1640 XL scan<sup>©</sup> (Seiko Epson Corp., Nagano, Japan). We used WinDENDRO<sup>©</sup> (Regent Instruments Inc., Canada) software to detect rings, but due to the characteristics of growth rings, the software was unable to automatically detect any ring. However, the agility and the ease-to-use of WinDENDRO<sup>©</sup> was of valuable help, so rings were manually marked, using both pencil marks – which were already scanned – and visual criteria through the screen. Ring-width data were cross-dated with COFECHA (Grissino-Mayer, 2001), and only the best correlated series were kept for building a master series for Peru ( $n = 96$ ) and Chile ( $n = 14$ ). To build this master series, the individual ring-width measurement series are standardized by removing the long-term growth trends largely attributed to increasing age and tree size (ARSTAN software). Detrending was done in two steps; first through a negative exponential curve, and second with a cubic smoothing spline (Fritts, 1976; Cook, 1985). Three chronologies result from this process: a standard chronology, a residual chronology (containing only the high-frequency variations) and the ARSTAN chronology (composed of the residual chronology with the pooled autoregression reincorporated). This last series containing the growth index is the one further used.

The two master chronologies (Peru and Chile) were matched against precipitation and temperature data. We used meteorological data from the Universidad de Piura for the Peruvian samples, and from La Serena Airport and the Vicuña weather stations for the Chilean one.

Tree recruitment years were directly obtained for those samples presenting the pith (tree centre), namely all disks from Peru and some *P. chilensis* tree cores. Using these Chilean samples, we related the distance to the pith with the number of years (no. of years =  $-1.6057 + 0.0608 \times \text{pith distance}$ ,  $R^2 = 0.993$ ,  $n = 13$ ). This regression was used to estimate the establishment date for the rest of the samples. In order to estimate the

distance to the pith in the cores that did not reach it, we used standard techniques consisting of matching the tree ring boundary closer to the pith against a template of circles at increasing radii.

For each species, we compared tree growth ( $\text{mm yr}^{-1}$ ) and recruitment (% of trees) in El Niño vs. non-El Niño years using a *t*-test. The chronology of *P. chilensis* was much longer than the one from *P. pallida* (1877–2001 vs. 1965–2001, respectively). As older trees are increasingly lost by natural mortality and this unknown factor may distort interpretation of the recruitment patterns, we repeated the same analysis using only the last 20 years data from the Peruvian and Chilean chronologies. We also explored the relationships between tree growth index and recruitment with annual rainfall and the southern oscillation index (SOI) at different time lags through a stepwise linear regression [i.e. tree growth index =  $f(\text{SOI}_t + \text{SOI}_{t-1} + \text{SOI}_{t-2})$ ].

## Field experiments

### Experiment 1: role of herbivory

This experiment aimed to test the role of herbivores on tree establishment during simulated rainy ENSO conditions. We performed our field experiments with *P. chilensis* in north-central Chile and *P. pallida* in north Peru. The herbivory treatments included plants exposed and not exposed to the local herbivores. In each region, we installed five  $6 \times 6 \text{ m}^2$  plots for each herbivore treatment. In Chile, main herbivores were European rabbits (*Oryctolagus cuniculus*) and hares (*Lepus europaeus*) and occasionally small native rodents (*Phyllotis darwini*, *Akodon olivaceus*, *Octodon degus*). In north Peru, main herbivores were native lizards (*Dicrodon gutulatum* and *Microlophus peruvianus*). All large herbivores, mainly domestic livestock, were excluded using a 800 m-perimeter fence around the whole experimental setting. To exclude small herbivores, we used 2 m high galvanized fences (0.5 cm mesh), buried 30 cm into the ground and with a 25 cm strip flashing at the upper part of the fence to exclude all small mammals. Before the start of the experiment, we live-trapped small mammals and lizards for 1 day using four traps per plot (160 traps in total) in order to control that no individuals were present in the herbivore-excluded experimental plots.

In north central Chile, the experiment was installed at the end of May 2002. After unsuccessful sowing, 25 *P. chilensis* plants were planted in each plot following a  $5 \times 5$  configuration, with 1 m distance between plants. We used 9-month-old plants, between 45 and 50 cm tall, obtained from a greenhouse of CONAF (Chilean Forest Service). Plants in the herbivore-exposed treatments

were temporarily protected with fences between planting and the beginning of the experimental treatments. In north Peru, the experiment was installed in December 2002. We sowed two seeds of *P. pallida* per future seedling point. Before sowing, seeds were water soaked at 35 °C for 24 h. After germination, we removed one seedling per sowing point to keep the same design used in Chile.

To simulate ENSO conditions, we watered all plants in addition to natural rainfall, adding 150 mm in Chile and 200 mm in Peru. The experimental irrigation was carried out during the rainy season in each locality following the natural distribution pattern of rainfall. We mimic natural rainfall by sprinkling water through nine 1 m height microjets per plot that were distributed at 2 m intervals. Considering the natural rainfall during the growing season and the water added, water availability in Chile reached 487 mm (337 mm natural rainfall), and 227.4 mm in north Peru (27.4 natural rainfall). The much higher values reached in Chile were produced by a coincident moderate ENSO event in 2002 (McPhaden, 2004). Plant survival percent at 6 months was compared between the two herbivory treatments at each site.

#### Experiment 2: role of water

This experiment was designed to study tree seedling establishment under a simulated range of ENSO intensities in the absence of herbivores. In each experimental site, we applied six water treatments in addition to natural rainfall (0, 50, 100, 200, 400, 600 mm). Treatments were replicated in 16 blocks. Drip irrigation was applied during the rainy season in each site using the natural distribution pattern of rainfall. The experimental setting was protected against large and small mammal herbivores using the method previously described for the herbivore control experiment. We removed the aboveground biomass of shrubs growing at the experimental set to avoid either uncontrolled shading and water effects by potential hydraulic lift (Squeo *et al.*, 1999).

In early September 2002, we planted 2-week old *P. chilensis* seedlings in Fray Jorge, and in December of that year we installed the experiment with *P. pallida* seedlings in Piura. Seedlings were 2 cm high and had emerged cotyledons. We monitored seedling survival and growth twice a month for 6 months. Plant survival percent was transformed (arcsine-square root) to correct for data distribution and water treatment effects were compared through a one-way ANOVA. Differences between treatment means were assessed by *a posteriori* Tukey test.

#### Experiment 3: role of plant growth rate

This field experiment compared the growth rate response of both species (*P. chilensis* and *P. pallida*) when grown under the same environmental conditions at both locations (Fray Jorge and Piura). We planted 25 one-week-old seedlings of each species in 10 replicated plots at each experimental site. The experiment was carried out between March and September 2003 in Piura, and between September 2003 and March 2004 in Fray Jorge. In each case, we simulated two rainfall events of 75 mm before plantation and 10 days afterwards, using the previously described drip irrigation method. All plants were protected against herbivores. Plant growth was monitored twice a month for 6 months. We used a factorial ANOVA to compare height growth between both species growing at the two experimental sites. Plots were nested within sites, and the proper error terms were used to test treatment effects.

## Results

#### Natural tree recruitment and growth: field patterns

The dendrochronological series of northwest Peru indicate that twice as many *P. pallida* trees were recruited during ENSO years compared with no-ENSO years, particularly for the last 20 years (Table 1). Around 33% of the trees were established during years with very high precipitation corresponding to strong or very strong ENSO events (Fig. 1, top panel).

**Table 1** Rainfall (mm ± SD), mean tree growth (mm ± SD) and mean tree recruitment (% ± SD) during ENSO and no-ENSO years for *Prosopis pallida* (Peru, 1965–2001) and *Prosopis chilensis* (Chile, 1877–2001)

	ENSO years	No-ENSO years	<i>P</i> value
Peru			
Rainfall	690.7 ± 952.6	39.9 ± 49.9	0.001
Growth	5.9 ± 3.6	3.2 ± 1.7	0.005
Recruitment	4.5 ± 4.2	2.4 ± 2.4	0.095
Growth (1980–2001)	7.0 ± 2.9	2.5 ± 1.0	0.001
Recruitment (1980–2001)	7.1 ± 3.5	3.5 ± 2.5	0.028
Chile			
Rainfall	174.1 ± 120.2	111.2 ± 85.6	0.003
Growth	1.9 ± 1.1	1.8 ± 0.9	0.845
Recruitment	0.43 ± 1.1	0.9 ± 1.6	0.161
Growth (1980–2001)	2.5 ± 0.4	2.1 ± 0.5	0.076
Recruitment (1980–2001)	0.30 ± 0.30	0.72 ± 0.32	0.556

For the whole series at each site, ENSO years are seven in Peru and 25 in Chile; and no-ENSO years are 27 in Peru and 100 in Chile.

ENSO, El Niño Southern Oscillation.

**Fig. 1** Annual rainfall, Southern Oscillation Index (SOI) and percentage of recruited *Prosopis pallida* trees in Peru (top panel) and *Prosopis chilensis* trees in Chile (bottom panel).

Tree-ring growth also doubled during ENSO years. In fact, during the last 2 decades the difference between growth in ENSO vs. no-ENSO years has increased to become 2.8 times greater during the rainy ENSO events (Table 1). This is also evident in the high correlation between tree-ring growth and annual precipitation (Pearson's Correlation 0.66,  $P < 0.01$ ), and the SOI (linear regression, all years,  $P = 0.05$ ; last 20 years,  $P = 0.03$ ). Growth was especially strong in 1983 and 1998, the years with the strongest ENSO events of the last century (Fig. 1, top panel).

In contrast, the tree-ring chronologies for *P. chilensis* showed no significant correlation between the percentage of trees established during certain year and the annual rainfall (Fig. 1, bottom panel). Also, we found no differences in tree growth between ENSO and no ENSO years when using the whole series, although there was a trend towards higher tree growth during ENSO events

in the last 2 decades (Table 1). We did find a significant correlation between growth and the SOI for both the whole series ( $P < 0.0001$ ) and the last 20 years ( $P < 0.0001$ ; Fig. 1, bottom panel). We also found a weak but significant correlation between tree-ring growth index and annual precipitation (Pearson's Correlation 0.365,  $P < 0.05$ , since 1957).

Growth rate of the two species were significantly different ( $t$ -test,  $P < 0.001$ ). Diameter growth rate of *P. pallida* was  $7.1 \pm 4.4 \text{ mm yr}^{-1}$  (1965–2001), while for *P. chilensis* was only  $4.5 \pm 3.7 \text{ mm yr}^{-1}$  (1915–2002). Differences were also significant when using data only from the last two decades ( $t$ -test,  $P = 0.03$ ).

#### Experimental results

Herbivory by native lizards in north Peru reduced *P. pallida* survival to only 31% in unprotected plots (Fig. 2).

**Fig. 2** Survival of *Prosopis pallida* (Peru) and *Prosopis chilensis* (Chile) growing in protected and unprotected plots under simulated rainy El Niño Southern Oscillation conditions after 6 months of plantation. Data are mean  $\pm$  SE ( $n = 5$  plots with 25 seedlings).

**Fig. 3** Survival of protected *Prosopis chilensis* (Chile) and *Prosopis pallida* (Piura) growing along a gradient of water availability after 6 months. We used six water treatments in addition to natural rainfall (0, 50, 100, 200, 400, 600 mm). Natural precipitation was 337 mm (Chile) and 27.4 mm (Peru). There were no statistical differences between treatment means in Peru. Same letters indicate no statistical differences between means in Chile. Data are mean  $\pm$  SE ( $n = 16$ ).

In north-central Chile, herbivory played an overwhelming role in the establishment of new trees, reducing survival of *P. chilensis* plants to just 3.6% in unprotected plots (Fig. 2). After almost 2 years, survival was reduced even further to only 0.3% (Gutiérrez *et al.*, 2007).

In the absence of herbivores, survival of *P. pallida* seedlings in Piura was very high under all water treatments (Fig. 3,  $F_{5,90} = 1.27$ ;  $P = 0.285$ ). With only 27 mm natural rainfall (no extra irrigation), survival was more than 85% after 6 months and remained this high after

**Fig. 4** Height of *Prosopis chilensis* and *Prosopis pallida* growing in Piura (Peru) and Fray Jorge (Chile) after 6 months. Data shows mean  $\pm$  SE ( $n = 10$  plots, with 25 seedlings each).

1 year in treatments that reached more than 90 mm of water availability during this whole period (Squeo *et al.*, 2007). In contrast, survival of *P. chilensis* seedlings was around six times lower and responded clearly to increasing water availability (Fig. 3;  $F_{5,90} = 6.67$ ,  $P < 0.001$ ). Seedling survival was near 10% with 450 mm or more after 6 months. After 1 year, no seedlings survived below 500 mm water availability and survival reached only 8% at higher water levels (Squeo *et al.*, 2007).

Both species grew much faster in northwest Peru than they did in north-central Chile (Fig. 4;  $F_{1,26} = 11.29$ ;  $P = 0.0024$ ). After 6 months, *P. chilensis* seedlings were 3.83 times taller in Peru than they were in Chile, and the *P. pallida* ones were 5.6 taller in Peru. There was no difference between species at each site ( $F_{1,26} = 1.06$ ;  $P = 0.3133$ ), and no interaction effects between species and site ( $F_{1,26} = 1.16$ ;  $P = 0.2916$ ).

## Discussion

ENSO events have profound effects on the dynamics of arid and semiarid ecosystems worldwide (Holmgren *et al.*, 2001, 2006). The rainy phases of this climatic oscillation can increase tree establishment and produce long-lasting ecosystem effects but the evidence varies across semiarid ecosystems (Holmgren & Scheffer, 2001). We hypothesized that these different outcomes could be explained by differences in herbivory and plant growth rate during the water pulses.

Our experiments show that in Chile, herbivory effects are a bottleneck for seedling survival. Even under high water availability conditions, no plants survived when unprotected. Main herbivores in Chile are European rabbits (*Oryctolagus cuniculus*) and hares (*L. europaeus*). These two species were introduced about a century ago and have proven to be extremely damaging for native

shrubs and trees (Fuentes *et al.* 1983, 1984; Jaksic & Fuentes, 1991). However, even when protected from herbivores, only around 8% of the 2-week-old *P. chilensis* seedlings survived at experimental water conditions equivalent to very strong Niño events in Chile (Fig. 3). Mortality dropped at older stages. Under the same experimental conditions, 9-month-old plants reached 100% survival (Fig. 2). Likely older plants can better cope with water stress and make better use of a water pulse than very young seedlings because of a better-developed root system. As our simulated rainy ENSO conditions in Chile were equivalent to very strong events, this suggests that windows of opportunity for tree establishment in Chile are very rare, and that prevalent environmental conditions are extremely hard for the recruitment of new trees.

The situation in Peru contrasts strongly to the Chilean conditions. The tree-ring data of northwest Peru indicate that twice as many *P. pallida* trees were recruited during ENSO years compared with no-ENSO years over the last 20 years. Also, tree mean annual growth rate is correlated with annual rainfall here, whereas in northern Chile we see no such relationship (López *et al.*, 2005, 2006). ENSO events are about 10 times stronger in northwest Peru than they are in north-central Chile. We could speculate that this difference in the rainy pulse intensity is the clue to understand the success of tree recruitment in Peru. However, our field experiments show that, when protected from herbivores, tree seedlings in northwest Peru can successfully establish with only 27 mm of precipitation, and that increased water availability does not significantly improve early survival. Intrinsic species differences do not seem to be an explanation for the successful tree establishment in Peru either. In fact, when both *Prosopis* species were planted together, they responded in comparable ways growing much faster in Peru than in Chile (Fig. 4).

All this indicates that overall environmental conditions for tree growth and establishment are much better in Peru. Even in the presence of herbivores, survival of *P. pallida* seedlings reached 31%, and when herbivores were absent, survival was close to 85% with only 27 mm of water. This suggests that environmental factors other than annual rainfall might be affecting plant growth and survival. Rainfall seasonality and temperature are likely crucial factors. The annual mean temperature is 24 °C in Peru with rainfall concentrated in summer months. In north-central Chile, with a mean annual temperature of only 13.6 °C and winter rainfall, plant growth is more than four times slower. It is possible that differences in soil texture between our study regions could reinforce differences in plant growth rate. Northwest Peru is characterized by more sandy soils with low resistance for root growth. Indeed root depth growth

after 1 year was over 100 cm in Piura compared with nearly half of that in north-central Chile (Squeo *et al.*, 2007). Desert sandy soils have higher infiltration rates and lower evaporation rates compared with heavier soils which could further favour root development (Noy-Meir, 1973).

The higher growth rates in Peru may allow a larger fraction of the seedlings to quickly reach a size at which they are less vulnerable to herbivory and drought. Fast root growth of *Prosopis* in north Peru may allow them to reach deeper water sources and overcome drought after the rainy ENSO events. Fast stem growth could also facilitate reaching a safer size against small herbivores such as lizards. Indeed, other studies have shown that plant growth rate and biomass allocation affect the capacity of tree seedlings to establish in the face of herbivory (Strauss & Agrawal, 1999) and drought (Lynch, 1995), and that as a result, the mortality rate among taller and older individuals tends to decrease (Toft, 1995; Watson *et al.*, 1997).

In addition to plant growth conditions, herbivore pressure may well be more benign in Peru than in Chile. Rabbits and hares are not only larger than lizards but they also have a browsing behavior that implies that plants are vulnerable to stem damage and potential death for longer periods. If we consider the slow plant growth rate in Chile, then is very likely that an escape from herbivory is extremely difficult.

Previous regional comparisons have established that water availability is a primary determinant of the potential woody cover that can be reached by semiarid systems (Sankaran *et al.*, 2005), but that actual woody cover depends also on disturbance regimes (herbivory and fire) and soil types (Scholes & Archer, 1997; Sankaran *et al.*, 2004). Our work illustrates this same principle, highlighting the importance of understanding the interplay of interannual variation in precipitation with herbivory for explaining successful tree recruitment. The combination of extreme rainy events with reduced herbivory seems to be key to understand woody cover expansion in many semiarid ecosystems. Some of the most striking examples have been described for semiarid Australia where the combination of rainy ENSO events with reduced grazing by either livestock or rabbits has repeatedly triggered the natural regeneration of *Eucalyptus* and *Callitris* woodlands (Austin & Williams, 1988). Similarly, the shrub expansion at the expense of dry grasslands in the Chihuahuan Desert over the past decades has been correlated with wetter winters associated to ENSO events (Brown *et al.*, 1997). Analyzing patterns on a longer time scale, Fredrickson *et al.* (2006) argued that ancient periods of woody cover expansion in the Chihuahuan Desert may be explained by drops in tree consumption (by Pleistocene fauna and

later indigenous people) combined with conditions that facilitated tree recruitment such as enhanced seed dispersion and favorable climatic conditions that improved tree establishment and survival.

In summary, our results indicate that ENSO rainy events might open windows of opportunity for tree recruitment in semiarid ecosystems depending on herbivore pressure and plant growth rate. These insights have two important implications. First, restoration programs of degraded semiarid landscapes could be coupled to the climatic swings depending on local conditions. Our results indicate that in regions such as northwest Peru, natural regeneration of dry forests is very likely. In regions such as north-central Chile, predicted rainy ENSO events could also have a positive effect on tree establishment but only if herbivores were actively controlled. Second, our results have implications for predictions of climate change effects. The last two decades have been marked by unusually strong and frequent El Niño events that suggest a potential human-induced greenhouse warming effect on the behavior of the ENSO phenomenon (Trenberth & Hoar, 1997; Tudhope *et al.*, 2001). If the frequency of El Niño events increases during the coming decades (Timmermann *et al.*, 1999), this will most probably result in an expansion of dry forests in certain semi-arid regions.

### Acknowledgements

We thank the careful review of the subject editor and two anonymous reviewers. We also thank Cajo ter Braak for advice on the statistical analyses and Marten Scheffer for his valuable insights. Carlos Gracia, Rodolfo Rodríguez and Santi Sabaté assisted on tree-ring data acquisition. Mario Matorel and Luis Albán helped on the field experiments in Peru. Rosa Manrique, José Reyes and Hernán Vásquez assisted on the field experiments in Chile. Frits (G. M. J.) Mohren and Percy Jiménez facilitated the co-ordination of tasks. This work was supported by the EU-INCO project ICA4-CT-2001-10051 ([www.biouls.cl/enso/](http://www.biouls.cl/enso/)). M. H. thanks also the dutch NWO Meervoud Program.
