15 **Boreal and arctic ecosystems are highly sensitive to climate change, with the northern high-**  
16 **latitude region warming faster than the global average (IPCC, 2013). Most previous studies**  
17 **on the response of the terrestrial carbon cycle to warming have focused on the net carbon**  
18 **uptake period (Lafleur et al., 2007; Richardson et al., 2009; Piao et al., 2017), while much less**  
19 **attention was paid on the dormant season, during which net carbon release occurs.**  
20 **Understanding how net carbon exchanges from the dormant season respond to warming is,**  
21 **however, equally crucial for forecasting ecosystem–carbon cycle feedbacks. Here, we present**  
22 **findings on the long-term effects of climate change on high-latitude ecosystem carbon cycle**  
23 **during the dormant season from the atmospheric CO<sub>2</sub> concentration record (Point Barrow,**  
24 **Alaska). We show that over the full study period (1974–2014), warming has significantly**  
25 **boosted autumn net carbon loss and advanced the CO<sub>2</sub> sink-source transition date, in line**  
26 **with previous analyses (Piao et al., 2008). However, in the second half of the study period, the**  
27 **atmospheric CO<sub>2</sub> record indicates no correlation between autumn net carbon loss and**  
28 **warming, which is further supported by analyses of net biome production from two different**  
29 **atmospheric inversion systems. Based on multiple sources of satellite-based productivity data,**  
30 **a suite of state-of-the-art ecosystem models and an atmospheric transport model, we further**  
31 **suggest that this deceleration of carbon losses with warming can be attributed to the loss of**  
32 **temperature dependency in respiration due to the soil moisture reduction, instead of**  
33 **changing temperature-productivity relationship, and changes in atmospheric transport,**  
34 **fossil fuel emissions and air-sea CO<sub>2</sub> exchanges. Our findings suggest that a warming climate**  
35 **does not necessarily result in a higher autumn CO<sub>2</sub> release, which offsets recently reported**  
36 **warming-induced loss of net carbon uptake during spring and summer seasons (Piao et al.,**  
37 **2017; Peñuelas et al., 2017) and therefore provide a negative feedback to climatic warming.**

38 The northern land region that includes the tundra and boreal forests is acknowledged to be an  
39 important component of the global carbon cycle, accounting for a considerable land-based sink for  
40 atmospheric CO<sub>2</sub> (McGuire et al., 2009; Pan et al., 2011). There is a wide recognition that climate  
41 change is having and will continue to have fundamental impacts on northern ecosystem carbon  
42 cycling and in turn on variations in atmospheric CO<sub>2</sub> (Beer et al., 2010; Keenan et al., 2014;  
43 McGuire et al., 2009; Heimann and Reichstein, 2008; Cox et al., 2000; Fiedlingstein et al., 2001;  
44 McGuire et al., 2009; Ahlström et al., 2012). Although studies of ecosystem responses to warming  
45 have mainly focused on spring and summer (Guerlet et al., 2013; Keenan et al., 2014; Piao et al.,  
46 2017), climate-carbon cycle interactions during the dormant season could be as crucial in  
47 modulating future climate change, due to the fact that a large portion of ecosystem carbon is stored  
48 in the soil (Wang et al., 2011; Commane et al., 2017), and a small fractional change in soil  
49 respiration with warming might significantly affect net ecosystem production and atmospheric CO<sub>2</sub>.  
50 However, we still lack the satisfactory assessment how the overall CO<sub>2</sub> exchange responds to  
51 climate change during the dormant season.

52  
53 Multiple lines of evidence that have recently emerged indicate that the response of carbon cycling  
54 to recent climate change since the late 1990s are different from the previous few decades (Piao et  
55 al., 2014; Piao et al., 2017; Peñuelas et al., 2017; Ballantyne et al., 2017). It has long been assumed  
56 that warming advances spring phenology and increases ecosystem carbon uptake (Keeling et al.,  
57 1996; Richardson et al., 2009). Although this was valid up to the 1990s, it no longer holds because  
58 of the weakening temperature control of spring net primary productivity (Piao et al., 2017).  
59 Furthermore, atmospheric CO<sub>2</sub> concentrations suggest that warm spring and summer-induced  
60 increases in annual CO<sub>2</sub> amplitude (the difference between the annual maximum and minimum  
61 concentrations within the same year), that could reflect the strength of net carbon uptake during

62 spring and summer disappeared in the last 17 years (Peñuelas et al., 2017). These multiple  
63 observational signals consistently reveal a shift in the warming effect on net carbon uptake from  
64 positive to neutral or even negative in spring and summer. However, it remains unclear how the  
65 effects of warming on net carbon release during the dormant season change with time. There is  
66 growing consensus that ecosystem productivity shows strong acclimation to warming (Oechel et  
67 al., 2000; Smith and Dukes, 2013), while respiratory flux to the atmosphere from ecosystem is  
68 anticipated to increase with warming. We therefore formulate the hypothesis that warming can  
69 accelerate net carbon loss during the dormant season and exacerbate negative warming impact on  
70 annual carbon sequestration.

71  
72 We studied this hypothesis by analyzing the relationship between indicators of net carbon release  
73 inferred from atmospheric CO<sub>2</sub> and temperature during the dormant season, and its temporal  
74 change over the period 1974–2014. We calculated partial correlation coefficient between net  
75 carbon release during the dormant season (defined as the change of CO<sub>2</sub> concentration from  
76 September to November for autumn and from December to next April for winter at Point Barrow,  
77 Alaska) and temperature in boreal and arctic ecosystems north of 50°N (through removing  
78 statistical influence of precipitation and cloudiness variations, as detailed in Methods). There is a  
79 tight relationship between autumn net carbon release (ACR) and temperature on the inter-annual  
80 timescale over the period 1974–2014 ( $R_{ACR-T} = -0.39$ ,  $P < 0.05$ ) (Figure S1), confirming that  
81 warming-induced increase in autumn respiration dominated over autumn photosynthetic gains  
82 (Piao et al., 2008; Miller, 2008). Unexpectedly,  $R_{ACR-T}$  changed from -0.62 ( $P < 0.01$ ) during  
83 1974–1996 to -0.05 ( $P = 0.85$ ) during 1997–2014, which runs counter to our proposed hypothesis  
84 that the negative temperature impact on annual carbon sequestration would recently become much

85 more pronounced. The observed diminished correlation between mean autumn temperature and  
86 ACR implies smaller land carbon release and reduced atmospheric CO<sub>2</sub> growth between September  
87 and November during warmer years. The sensitivity of ACR to autumn temperature ( $\gamma_{ACR-T}$ ) shifts  
88 from -1.09 ppm K<sup>-1</sup> during the earlier period to -0.11 ppm K<sup>-1</sup> during later period (Figure S2), with  
89 change in magnitude of 0.98 ppm K<sup>-1</sup>, indicating a change in sensitivity of about 2.09 gigatonnes  
90 of carbon per year per K when calculating based on a conversion factor of 2.14 GtC ppm<sup>-1</sup> (IPCC,  
91 2013). This diminished negative temperature effect on autumn carbon cycle is also detected in the  
92 upward zero-crossing date of CO<sub>2</sub> (defined as the day when detrended seasonal CO<sub>2</sub> crosses the  
93 zero line from the negative to positive value). In the earlier period warmer years implied earlier  
94 crossing dates ( $R = -0.66$ ,  $P < 0.01$ ), while in the later period no correlation remained ( $R = -0.02$ ,  
95  $P = 0.95$ ) (Figure S3). In contrast to autumn, in winter no temperature response of ACR was  
96 detected, neither in the earlier period ( $R = 0.11$ ,  $P = 0.63$ ), nor in the later period ( $R = -0.04$ ,  $P =$   
97  $0.89$ ) (Figure 1c).

98  
99 To test the robustness of the observed decelerated loss of warming impact on autumn ACR, we  
100 performed the following additional analyses: (1) we defined autumn as the period from September  
101 1<sup>st</sup> to the date when detrended seasonal CO<sub>2</sub> crosses the zero line from the negative to positive  
102 value (Figure S4), (2) we used another climate dataset (WFDEI, see Methods, Figure S5) and (3)  
103 we used CO<sub>2</sub> concentration records from weekly *in situ* measurements and flask samples (see  
104 Methods, Figure S6). All of these analyses confirmed that autumn warming no longer accelerates  
105 autumn net carbon release in the latest period. In a consistent manner, we also analyzed the  
106 temporal change in temperature dependence of net biome production (NBP) from two different  
107 atmospheric inversion systems. Consistent with the atmospheric CO<sub>2</sub> analyses, NBP from the Jena  
108 CarboScope inversion system also indicated a non-significant temperature impact on autumn NBP

109 over boreal and arctic ecosystems north of 50°N during 1997–2011 ( $R = -0.44 \pm 0.13$ ), in contrast  
110 to the significant temperature effect found during 1982–1996 ( $R = -0.74 \pm 0.05$ ) (Figure 2a).  
111 Similar results were also found if NBP from MACC inversion system was considered (1982–1996:  
112  $R = -0.65 \pm 0.08$ ; 1997–2011:  $R = -0.16 \pm 0.15$ , Figure S7). Besides land ecosystems, atmospheric  
113 CO<sub>2</sub> variation also harbors signals from changes in atmospheric transport, air-sea CO<sub>2</sub> exchanges  
114 and fossil fuel emissions. We therefore assessed their potential contributions to the change in  $R_{ACR-T}$   
115 using atmospheric transport simulations based upon atmospheric transport model from the  
116 Laboratoire de Météorologie Dynamique (LMDz) (Hourdin et al., 2006) (see Methods), and found  
117 that their decadal changes would not contribute to the observed diminished temperature control on  
118 ACR (Figure S8).

119  
120 Which terrestrial carbon cycle processes caused the diminished negative temperature control on  
121 the autumn carbon cycle in the north? This diminished effect could be only explained by an  
122 enhanced temperature reliance of carbon uptake through vegetation photosynthesis and/or a  
123 reduced temperature dependence of carbon loss through respiration. Analysis of satellite-based  
124 vegetation index (GIMMS NDVI) (Tucker et al., 2005) as a proxy for vegetation production  
125 showed that autumn NDVI is marginally significantly correlated with temperature in the earlier  
126 period ( $R = 0.50 \pm 0.15$ ), but became decoupled from temperature in the later period ( $R = -0.37 \pm$   
127  $0.14$ ) (Figure S9). This weakened temperature dependence of vegetation production was,  
128 nonetheless, also evident when considering satellite-based estimates of net primary productivity  
129 (NPP) (Smith et al., 2016, Figure 2b), or satellite-independent estimates of gross primary  
130 productivity (GPP) up-scaled from eddy flux towers (Jung et al., 2009)(Figure S10), thereby ruling  
131 out its possibility in explaining the diminished temperature effect on ACR. For example,  $R_{NPP-T}$

132 and  $R_{GPP-T}$  decreased from  $0.82 \pm 0.06$  and  $0.88 \pm 0.04$  in the earlier period to  $0.41 \pm 0.23$  and  $0.43$   
133  $\pm 0.14$  in the later period, respectively.

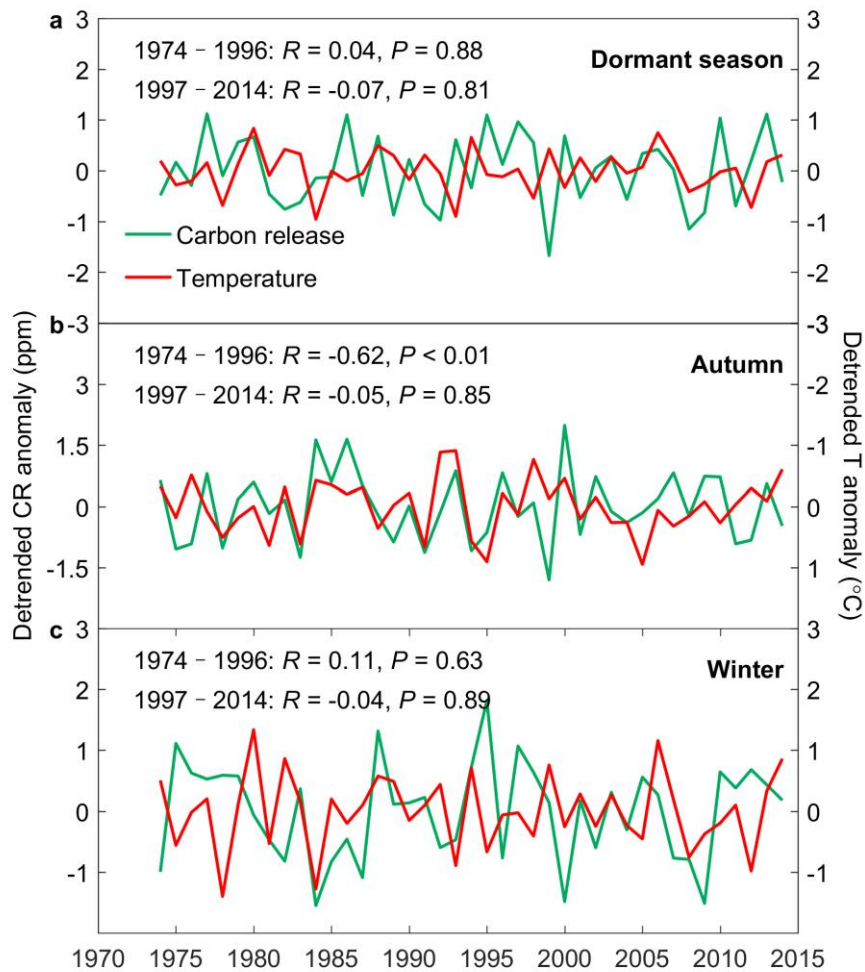

134  
135 The heterotrophic respiration (HR), computed as the difference between NBP from Jena  
136 CarboScope (or MACC) dataset and satellite-derived NPP, has significant partial correlations with  
137 autumn temperature in the earlier period (Jena:  $R_{HR-T} = 0.90 \pm 0.03$ ; MACC:  $R_{HR-T} = 0.79 \pm 0.06$ )  
138 but not in the later period (Jena:  $R_{HR-T} = 0.48 \pm 0.14$ ; MACC:  $R_{HR-T} = 0.28 \pm 0.15$ ) (Figure 2c,  
139 Figure S7b). Furthermore, we also analyzed simulated HR from eight models participating in the  
140 historical climate carbon cycle model intercomparison project (TRENDY, see Methods), and found  
141 that the strong HR-temperature correlation in the earlier period also became weak and non-  
142 significant during the later period across almost all of the models (Figure S11 and S12). Therefore,  
143 we conclude that the diminished negative temperature effect on autumn carbon cycle during the  
144 latest period is most likely due to diminished temperature dependence of respiratory losses. To  
145 diagnose the potential mechanism responsible for the decrease in  $R_{HR-T}$ , we studied decadal changes  
146 in simulated soil moisture content from TRENDY models, and found a widespread reduction in  
147 soil moisture particularly over North America and Siberia, which was spatially coherent with the  
148 decline in  $R_{HR-T}$ , suggesting the plausibility of a potential soil water effect (Figure S13).

149  
150 We provide the evidence that autumnal warming no longer accelerates net carbon losses and  
151 advance the end of the carbon uptake period in boreal and arctic ecosystem as previously suggested  
152 (Piao et al., 2008; Ueyama et al., 2014), primarily through reducing positive decomposition  
153 responses to warming most likely due to a soil moisture shortage. The autumnal finding reveals the  
154 similar temperature-dependent shift in carbon cycle over the last 3 decades that is also found to  
155 occur in the main growing season (Peñuelas et al., 2017; Piao et al., 2017), suggesting a changing

156 paradigm for temperature control over ecosystem carbon cycling. However, the outcomes of these  
157 shifts on net CO<sub>2</sub> exchanges are not consistent in the direction of their effect on atmospheric pCO<sub>2</sub>  
158 and would thus partly compensate for each other. The autumnal respiratory acclimation has an  
159 ameliorating impact on net CO<sub>2</sub> losses with rising temperatures, which could offset the negative  
160 warming impact on net CO<sub>2</sub> uptake during the active growing season (Peñuelas et al., 2017; Piao  
161 et al., 2017). It is therefore premature to conclude that the impact of temperature on annual carbon  
162 cycle has fundamentally shifted towards the negative state, and highlights the importance of  
163 incorporating how net carbon losses change with temperature during the dormant period in fully  
164 understanding temperature impacts on net carbon uptake. Additional studies are still needed to  
165 quantify whether these two opposing effects on carbon cycle will effectively neutralize each other,  
166 particularly for arctic and boreal ecosystems where the majority of permafrost soil carbon is stored  
167 and increasing old soil carbon will be respired to the atmosphere as a result of warming-induced  
168 permafrost thaw (Schuur et al., 2015; Pries et al., 2016; Koven et al., 2011).

169 **Figure 1. Temperature control on net carbon release during the dormant season.** Here we  
170 define the dormant season as the period from September to next April (**a**), which consists of autumn  
171 (September to November, **b**) and winter (December to next April, **c**). The lines are time series of  
172 the detrended anomaly of net carbon release (green) and mean temperature across land ecosystems  
173 north of 50°N (red).

174

175

176 **Figure 2. The relationship between ecosystem carbon fluxes and temperature in autumn.** (a-  
 177 c), the frequency distribution of the partial correlation coefficient of net biome production (NBP),  
 178 net primary productivity (NPP), and heterotrophic respiration (HR) with average temperature  
 179 during September to November across land ecosystem north of 50°N, whilst controlling for  
 180 precipitation and cloudiness during the earlier period (1982–1996, blue bar) and later period  
 181 (1997–2011, red bar), respectively. For each period, we randomly selected 12 years to generate the  
 182 frequency distribution of partial correlation coefficient. The shade illustrates the significance level  
 183 at  $P < 0.05$  (magenta) and  $P < 0.10$  (green), respectively. (d-f), the spatial distribution of the  
 184 changes in the partial correlation coefficient of NBP, NPP and HR with temperature for the two  
 185 periods, respectively. Here NBP is estimated from Jena CarboScope inversion system, the NPP is  
 186 estimated based on GIMMS NDVI, and HR was calculated as the difference between NBP and  
 187 NPP.

189 **Figure 3. Schematic of the effect of warming on seasonal CO<sub>2</sub> uptake and release.** In spring,  
 190 warming advances the source-to-sink transition date and increases CO<sub>2</sub> uptake that decreases  
 191 atmosphere CO<sub>2</sub> (Keeling et al., 1996), but which disappeared in the later period (1996–2012)  
 192 (Piao et al., 2017). In summer, the effect of warming on net CO<sub>2</sub> uptake became significantly  
 193 negative in the later period that increases atmosphere CO<sub>2</sub> (Peñuelas et al., 2017). On the contrary,  
 194 the widely recognized autumn warming-induced advancement in sink-to-source transition date and  
 195 acceleration in net CO<sub>2</sub> release (Piao et al., 2008) became diminished in the later period, which  
 196 could decrease build-up of atmospheric CO<sub>2</sub>. In contrast, the temperature effect on winter net CO<sub>2</sub>  
 197 release is not significant during both periods.

198

199 **Materials and Methods**

200 **Atmospheric CO<sub>2</sub> concentration**

201 The CO<sub>2</sub> concentration records from Point Barrow (71°N, Alaska) cover the period from 1974 to  
202 2014, and are derived from the National Oceanic and Atmospheric Administration (NOAA) Earth  
203 System Research Laboratory (Thoning et al., 2014). The CO<sub>2</sub> concentration time series consist of  
204 three types of signals: the long-term trend, the short-term variations, and the seasonal cycle. We  
205 performed the following procedure to obtain detrended seasonal cycle of CO<sub>2</sub> concentration. First,  
206 we fitted the daily CO<sub>2</sub> records using a function consisting of four harmonics and a quadratic  
207 polynomial to separate the seasonal cycle from the long-term increasing trend (Thoning et al, 1989)  
208 and obtain the residuals from this function fit. Second, we used a 1.5 month (or 1 month, see Figure  
209 S6) full-width half-maximum value (FWHM) averaging filter to remove the short-term variations  
210 from the residuals and get a smoothed curve by adding the filtered residuals to the fitted function  
211 in the first step. We also applied a 390-day FWHM averaging filter to derived residuals from the  
212 first step and added the filtered residuals to the fitted long-term trend from quadratic polynomial  
213 to obtain a de-seasonalized long-term trend. Finally, we calculated the difference between the  
214 smoothed curve and the de-seasonalized long-term trend as the detrended seasonal CO<sub>2</sub>  
215 concentration. As outlier records have strong influence on the fitting process, we repeatedly fitted  
216 the CO<sub>2</sub> time series as described in the first step and discarded records lying outside five times of  
217 standard deviation of the residuals until no outliers were found (Harris et al, 2000).

218

219 We define the dormant season as the period from September to next April and calculated the  
220 changes in detrended CO<sub>2</sub> concentration during this period (CO<sub>2</sub> concentration in the last week of  
221 April in next year minus that in the first week of September) as the dormant season net carbon

222 release (CR). We also separate the dormant season into autumn (September to November) and  
223 winter (December to next April) and calculated autumn carbon release (ACR) and winter carbon  
224 release (WCR) as the changes of CO<sub>2</sub> concentration in autumn and winter, respectively. In addition,  
225 the mean date when detrended seasonal CO<sub>2</sub> crosses zero line from the negative to positive value  
226 is around the 317<sup>th</sup> day of the year (DOY) during the period from 1974 to 2014. To test the  
227 robustness of the analysis, we also defined autumn as the period from the first day of September to  
228 DOY 317 and defined winter as the period from DOY 318 to the last day of April in next year and  
229 calculated ACR and WCR accordingly. Furthermore, we also calculate CR from the weekly  
230 atmospheric CO<sub>2</sub> concentration from the NOAA Earth System Research Laboratory at Barrow.

231

### 232 **Climate dataset**

233 We used the monthly climate dataset from the Climate Research Unit, University of East Anglia  
234 (CRU TS4.0 dataset) (Mitchell et al, 2005) in this study. This dataset covers the period from 1901  
235 to 2015, with a spatial resolution of 0.5°×0.5°. We selected mean temperature, precipitation and  
236 cloud cover for the analysis. We also used another climate dataset, which applied the WATER and  
237 global Change (WATCH) Forcing Data to the ERA-Interim dataset ([http://www.eu-  
238 watch.org/gfx\\_content/documents/README-WFDEL.pdf](http://www.eu-watch.org/gfx_content/documents/README-WFDEL.pdf)) for the analysis and obtained similar  
239 results (Figure S5).

240

### 241 **Vegetation production datasets**

242 We used the Normalized Difference Vegetation Index (NDVI) retrieved from the third-generation  
243 of the Advanced Very High Resolution Radiometer (AVHRR) developed by the Global Inventory  
244 Modeling and Mapping Studies (GIMMS) group (version 3g.v0, available at

245 <https://ecocast.arc.nasa.gov/data/pub/gimms/3g.v0>) as a proxy for vegetation activity (Tucker et al,  
246 2005). The GIMMS NDVI dataset covers the period from 1982 to 2013, with a spatial resolution  
247 of  $0.083^{\circ} \times 0.083^{\circ}$ . We also used two vegetation production data: the monthly GIMMS net primary  
248 production (NPP) dataset (Smith et al, 2016), and the gross primary productivity (GPP) up-scaled  
249 from eddy flux towers using multi-tree ensemble approach (Jung et al, 2009).

250

### 251 **Atmospheric CO<sub>2</sub> inversion data**

252 We gathered two atmosphere CO<sub>2</sub> inversion products to investigate the response of terrestrial  
253 carbon fluxes to warming. We used monthly net biome production (NBP) from the Jena  
254 CarboScope (<http://www.bgc-jena.mpg.de/CarboScope/>, version s81\_v3.8) for the period from  
255 1982 to 2011, with a spatial resolution of  $3.75^{\circ}$  latitude  $\times 5^{\circ}$  longitude. The monthly net biome  
256 production (NBP) from the Monitoring Atmospheric Composition and Climate (Chevallier et al,  
257 2005) (MACC, version v14r2, <http://copernicus-atmosphere.eu/>) between 1979 and 2011 was also  
258 used for the analysis. We calculated the heterotrophic respiration as the difference between  
259 inversed NBP and satellite-based NPP.

260

### 261 **Terrestrial ecosystem models**

262 Simulation results of eight models from a historical climate carbon cycle model inter-comparison  
263 project (Trendy) were used in this study. These models are Community land Model Version 4.5  
264 (CLM4.5), the Integrated Science Assessment Model (ISAM), the Joint UK Land Environment  
265 Simulator (JULES), Lund-Potsdam-Jena DGVM (LPJ), Lund-Postam-Jena General Ecosystem  
266 Simulator (LPJ-GUESS), the Land surface Processes and eXchanges (LPX), the Organizing  
267 Carbon and Hydrology In Dynamic Ecosystems (ORCHIDEE), and the Vegetation Integrative  
268 Simulator for Trace gases (VISIT). All the models used forcing data from CRUNCEP dataset, and

269 the simulation setup follow the standard protocol described in the inter-comparison project  
270 ([http://dgv.m.ceb.ac.uk/files/Trendy\\_protocol%20Nov2011\\_0.pdf](http://dgv.m.ceb.ac.uk/files/Trendy_protocol%20Nov2011_0.pdf)). Here we used the S2  
271 simulations, which consider the effect of climate change and rising CO<sub>2</sub> concentration on  
272 ecosystem carbon fluxes.

273

274 **Effects of atmospheric transport, air-sea CO<sub>2</sub> exchanges and fossil fuel emission on the**  
275 **change in autumn net CO<sub>2</sub> release**

276 To investigate the effects of atmospheric transport, air-sea CO<sub>2</sub> exchanges and fossil fuel emission  
277 on the change in autumn net carbon release, we assessed the impact of year-to-year variations in  
278 atmospheric transport, air-sea CO<sub>2</sub> exchange and fossil fuel emission on the observed changes on  
279 autumn net carbon release between the early period (1979–1996) and the later period (1997–2012)  
280 using atmospheric transport simulations. We used LMDz4, a 3D atmospheric tracer transport  
281 model from the Laboratoire de Météorologie Dynamique (Hourdin et al., 2006), nudged with  
282 ECMWF winds. As boundary conditions for transport simulations, we use land carbon fluxes over  
283 1979–2012 from the land surface model ORCHIDEE (Krinner et al., 2005) that is driven by  
284 observed atmospheric CO<sub>2</sub> concentration and historical climate forcing from the CRU-NCEPv4  
285 climate variables at 6-h resolution (Viovy and Ciais, 2014). For air–sea CO<sub>2</sub> exchanges, we use  
286 simulations from a biogeochemical model PlankTOM5 combined with a global ocean general  
287 circulation model NEMO (NEMO-PlankTOM5) that is forced by inputs of ions and compounds  
288 from river, sediment and dust for the PlankTOM5 model, and daily wind and precipitation from  
289 the NCEP reanalysis for the NEMO model (Buitenhuis et al., 2010). For fossil fuel CO<sub>2</sub> emissions,  
290 the monthly global time series was derived from the Carbon Dioxide Information Analysis Center  
291 (CDIAC) website (<http://cdiac.esd.ornl.gov>) (Andres et al,2011).

292  
293 To assess whether changes in atmospheric transport can influence the observed change in ACR,  
294 we perform the transport modeling experiment in which land and air–sea CO<sub>2</sub> exchanges are fixed  
295 at the year 1979 but the atmospheric transport allows to be varying according to ECMWF wind  
296 fields (refer to WCC hereafter). For air–sea CO<sub>2</sub> exchange, we conduct the modeling experiment  
297 where the atmospheric transport and land carbon fluxes are fixed at year 1979 but air–sea CO<sub>2</sub>  
298 exchanges vary according to simulations from NEMO-PlankTOM5 (WAC simulation). To assess  
299 the effect from fossil fuel emission, we conducted the modeling experiment where the land and air-  
300 sea CO<sub>2</sub> exchanges fixed at the year 1979, but transport the year-to-year varying fossil fuel  
301 emission (WCF simulation).

302  
303 **Analysis**  
304 We performed partial correlation analysis between net carbon release during the dormant season  
305 (autumn and winter) with temperature whilst statistically controlling for precipitation and cloud  
306 cover ( $R_{CR-T}$ ,  $R_{ACR-T}$ , and  $R_{WCR-T}$ ). The climate variables are averaged over the region north of 50°N,  
307 and we only considered the pixels where the annual NDVI greater than 0.1. The partial correlation  
308 analysis was performed for the earlier period (1974-1996) and later period (1997-2014)  
309 respectively. All variables are detrended before the partial correlation analysis. For a more robust  
310 analysis, we also performed the partial correlation analysis through randomly selecting 12 years  
311 from the time series among the corresponding period to generate a frequency distribution of the  
312 partial correlation coefficient. We also conducted a two-sample *t*-test to determine whether the  
313 partial correlation coefficient is statistically significant. To test if the shift of  $R_{ACR-T}$  is influenced  
314 by atmospheric transport, we calculated ACR from the WCC simulation, which all factors except  
315 wind field are fixed to year 1979, to denote the effect from atmospheric transport. To test if the

316 shift of  $R_{ACR-T}$  is influenced by the transport of air-sea CO<sub>2</sub> and fossil fuel emission, we calculated  
317 the air-sea CO<sub>2</sub> and fossil fuel induced ACR by calculating the difference between the WAC (WCF)  
318 and the WCC simulation. Then we conducted the partial correlation analysis on the WAC (WCF)  
319 induced ACR. To investigate the driver of the shift of  $R_{ACR-T}$ , we also performed the same analysis  
320 to the satellite-derived NDVI ( $R_{NDVI-T}$ ), the satellite-based NPP ( $R_{NPP-T}$ ), the flux-tower based GPP  
321 ( $R_{GPP-T}$ ), the inversed NBP ( $R_{NBP-T}$ ) and the HR calculated from NBP and NPP ( $R_{HR-T}$ ).
