3 ABSTRACT: The electronic and optical properties of two-dimensional layered materials allow
4 the miniaturization of nanoelectronic and optoelectronic devices in a competitive manner. Even
5 larger opportunities arise when two or more layers of different materials are combined. Here we
6 report on an ultrafast energy efficient strategy, using laser irradiation, which allows bulk
7 synthesis of crystalline single-layered lead iodide in the cavities of carbon nanotubes by forming
8 cylindrical van der Waals heterostructures. In contrast to the filling of van der Waals solids into
9 carbon nanotubes by conventional thermal annealing, which favors the formation of inorganic
10 nanowires, the present strategy is highly selective towards the growth of monolayers forming
11 lead iodide nanotubes. The irradiated bulk material bearing the nanotubes reveals a decrease of
12 the resistivity as well as a significant increase in the current flow upon illumination. Both effects
13 are attributed to the presence of single-walled lead iodide nanotubes in the cavities of carbon
14 nanotubes, which dominate the properties of the whole matrix. The present study brings in a
15 simple, ultrafast and energy efficient strategy for the tailored synthesis of rolled-up single-layers
16 of lead iodide (*i.e.* single-walled PbI_2 nanotubes), which we believe could be expanded to other
17 two-dimensional (2D) van der Waals solids. In fact, initial tests with ZnI_2 already reveal the
18 formation of single-walled ZnI_2 nanotubes, thus proving the versatility of the approach.

1
2
3 Two-dimensional layered materials have become a major focus of research because of their
4 extraordinary properties.¹⁻⁴ The high flexibility of single-layered crystals allows rolling them up
5
6 to form tubular structures which combine the properties of both two-dimensional and one-
7
8 dimensional materials, further expanding their range of application.⁵ Strain engineering can be
9
10 accomplished by bending two-dimensional materials allowing a fine tuning of their properties.⁶
11
12 For example, rolling up MoS₂ sheets induces a tunable semiconducting to metallic phase
13
14 transition,⁷ and an enhanced photoabsorption when integrated into rolled-up heterostructures
15
16 compared to their "flat" configuration.⁸ Scrolled graphene/polycarbonate fibers show exotic
17
18 telescoping elongation at break 30 times greater than Kevlar.⁹ Apart from nanoscrolls, cylindrical
19
20 two-dimensional materials (*i.e.* nanotubes) are formed when two parallel edges are seamlessly
21
22 joined. Edge states have a strong effect on the electronic properties of two-dimensional
23
24 materials.¹⁰ Cylindrical 2D materials are being explored for nanophotonic circuitry because
25
26 compressing and channeling of plasmons suffer from scattering at the edges of 2D sheets.¹¹ From
27
28 just these few examples it is clear that single-layered nanotubes, commonly referred to as single-
29
30 walled nanotubes, are of great interest for technological applications. However, despite efforts on
31
32 the synthesis of nanotubes started more than a decade before the interest on their two-
33
34 dimensional "flat" analogues, the amount of single-walled inorganic nanotubes reported to date
35
36 is limited because their multi-walled counter parts are favored during synthesis.¹² The synthesis
37
38 of elusive single-walled inorganic nanotubes remains as a grand challenge.¹³ Therefore,
39
40 strategies are needed to fill this gap. A variety of single-walled nanotubes with a high catalytic
41
42 performance,^{14, 15} not restricted to layered structures in their bulk form, have recently been
43
44 synthesized taking advantage of weak interactions between building blocks.¹⁴⁻¹⁶ When it comes
45
46 to the synthesis of single-walled nanotubes of van der Waals solids, which are the scope of the

2
3 present study, we recently reported on the use of carbon nanotubes for the template directed
4 growth of single-walled materials in their interior.¹⁷ The synthetic strategy proved to be versatile
5 but requires the use of high temperatures for prolonged periods of time. Furthermore, even under
6 the best synthetic conditions, a large fraction (at least 35 %) of other nanostructures are formed
7 in the interior of the carbon nanotubes¹⁸ which could strongly influence the properties. Here we
8 present an ultrafast, energy efficient and easily scalable approach that allows the selective
9 synthesis of single-walled lead iodide nanotubes coating the inner walls of carbon nanotubes,
10 thus forming cylindrical van der Waals heterostructures. By exploiting the properties of van der
11 Waals heterostructures, a variety of designs and devices emerge.^{19, 20} For instance, the
12 combination of graphene with light-sensitive materials allows the creation of efficient
13 photodetectors²¹ and photoresponsive memory devices.²² We focused the present study on the
14 growth of monolayers of lead iodide since this material is of interest not only as a room-
15 temperature detector of γ - and X-radiation²³ but has also become a strategic material for hybrid
16 solar cells.²⁴ Actually, interfacing electrically active graphene with light sensitive lead iodide has
17 been predicted to substantially enhance its visible light response.²⁵ To complete the study, the
18 optoelectronic properties of the resulting heterostructures embedded in the bulk matrix of lead
19 iodide have been investigated. Remarkably, whereas lead iodide monolayers must be handled
20 under inert atmosphere to avoid decomposition,²⁶ the composite materials prepared here can be
21 handled in air since the carbon shell offers protection to the lead iodide single-layers.

49 RESULTS AND DISCUSSION

50
51 **Laser-Assisted Filling of Carbon Nanotubes.** The encapsulation of materials into the cavities
52 of previously synthesized carbon nanotubes (CNTs) requires that the filling material either melts
53
54
55
56
57
58
59
60

1
2
3 or sublimes to allow its incorporation when using high temperature filling strategies.²⁷⁻³⁰
4
5 Alternatively, solution filling can be employed but lower filling yields are generally reported and
6
7 further processing is required to eliminate the solvent, unless the solvent itself is the chosen
8
9 material.³¹⁻³⁴ The controlled synthesis of materials within the cavities of CNTs is getting an
10
11 increased attention,³⁵⁻³⁷ and for instance MoS₂ and WS₂ nanoribbons have been prepared in this
12
13 manner.^{27, 38} Laser irradiation of materials can lead to a fast and local increase of the temperature
14
15 and arises as a promising alternative to the conventional annealing using furnaces that have been
16
17 widely employed to achieve molten phase capillary filling.³⁹⁻⁴¹ Lead iodide single-walled
18
19 nanotubes were grown by laser irradiation of a pellet consisting of open-ended multi-walled
20
21 carbon nanotubes (MWCNTs) finely mixed with lead iodide powder. A schematic representation
22
23 of the employed process is shown in Figure 1A. Pellets of 1.3 cm in diameter and ca. 0.5 mm in
24
25 thickness were prepared by applying a pressure of 10 T to the MWCNT/PbI₂ mixture. A variety
26
27 of incident laser fluences (40-100 mJ·cm⁻²) was employed using different number of pulses (10,
28
29 100 and 1000 pulses per site). Photothermal simulations were initially performed to obtain
30
31 information about the temporal evolution of the temperature reached by the target during the
32
33 irradiation with different laser fluences in the 40-100 mJ·cm⁻² range. An idealized system,
34
35 composed of a MWCNT immersed in a PbI₂ matrix was employed. Figure 1B shows that the
36
37 melting temperature of PbI₂ (T_m = 410 °C,⁴² purple dashed line) would be already exceeded even
38
39 at the lowest considered laser fluence (530 °C, 40 mJ·cm⁻²), exhibiting extremely high heating-
40
41 cooling rates (up to ca. 2×10⁹ °C·s⁻¹). In these conditions, the maximum temperature is close to
42
43 the temperature previously employed for the synthesis of PbI₂ nanotubes by conventional
44
45 annealing treatments (500 °C).¹⁷ The peak temperature is reached at about 4 ns and increases
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 with the applied laser fluence. The maximum achieved temperature with the current strategy
4
5 would be ca. 950 °C, after irradiation at 100 mJ·cm⁻².
6

7
8 **Structural Analysis of Cylindrical van der Waals Heterostructures.** Analyses of the laser
9
10 irradiated samples by back-scattered scanning electron microscopy (SEM), which provides Z-
11
12 contrast images of the samples, indicated that filling of the CNTs occurred in the whole range of
13
14 laser fluences and number of accumulated pulses (Figure S1). A small fraction of the pellet
15
16 irradiated at different laser fluences and pulses was gently scratched and characterized by high-
17
18 angle annular dark field (HAADF) imaging in high resolution scanning transmission electron
19
20 microscopy (STEM). Regardless of the laser fluence (40-100 mJ·cm⁻²) and pulses employed (10,
21
22 100 and 1000 pulses) the vast majority of MWCNTs that were filled with PbI₂ presented the
23
24 characteristic contrast of PbI₂ nanotubes and a minority of them revealed the presence of PbI₂
25
26 nanowires. A representative HAADF-STEM image providing a general view of the sample
27
28 prepared at 80 mJ·cm⁻² fluence and 1000 pulses is presented in Figure 2A and additional images
29
30 are included in Figure S2. Since HAADF-STEM imaging is strongly dependent on the atomic
31
32 number Z,⁴³ heavy elements such as Pb (Z = 82) and I (Z = 53) appear with a bright contrast,
33
34 whereas carbon (Z = 6) appears as pale grey. As it can be seen in the images, the inner cavities of
35
36 the hosting CNTs are contoured by bright lines indicating the successful formation of single-
37
38 walled PbI₂ nanotubes in their interior. At low laser fluences the observed inorganic PbI₂
39
40 presented a more defective/fractioned structure than at higher fluences. Figure S3 shows
41
42 HAADF-STEM images of the sample prepared at 40 mJ·cm⁻² fluence and 1000 pulses. Visual
43
44 inspection of the irradiated pellet already reflects the cumulative effect of increasing the number
45
46 of laser pulses (Figure S4). Thus, the highest amount of PbI₂ filled MWCNTs would be expected
47
48 at 1000 pulses. A quantitative determination of the ratio between filled and empty MWCNTs is
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 not possible since the irradiated areas were manually scratched for HAADF-STEM inspection.
4
5 During this process non-irradiated areas could be also collected and imaged.
6

7
8 It is worth stressing that all the inorganic PbI_2 nanotubes imaged in the present study (over
9
10 1000) are single-walled. The presence of multi-walled PbI_2 was not observed regardless of the
11
12 laser fluence and pulses employed. Two additional samples were prepared to assess whether the
13
14 use of higher fluence ($200 \text{ mJ}\cdot\text{cm}^{-2}$, 1000 pulses) or number of pulses (10000 pulses, $100 \text{ mJ}\cdot\text{cm}^{-2}$)
15
16 ²) would favor the formation of multi-walled PbI_2 . Despite the extremely high temperature
17
18 developed in the material at $200 \text{ mJ}\cdot\text{cm}^{-2}$ (ca. $1700 \text{ }^\circ\text{C}$ according to simulation, Figure S5) and
19
20 much longer irradiation time, analyses of the irradiated areas by HAADF-STEM revealed the
21
22 absence of multi-walled nanotubes.
23
24
25

26 We also investigated the stability of the confined monolayers one year after their synthesis.
27
28 Samples were kept under ambient conditions, thus exposed to humidity and air. Despite PbI_2 is a
29
30 rather unstable material which can decompose gradually in wet air,²⁶ HAADF-STEM imaging
31
32 reveals the presence of PbI_2 nanotubes still inside the cavities of CNTs with only partial damage
33
34 in some areas (Figure S6; $80 \text{ mJ}\cdot\text{cm}^{-2}$ fluence and 1000 pulses). This microscopy analysis
35
36 confirms that MWCNTs not only act as templates for the growth of tubular inorganic
37
38 nanostructures, but also offer shielding and protection of the inner PbI_2 nanotubes from the
39
40 external environment. This is a major advantage compared to physical vapor deposition grown
41
42 PbI_2 layers where the synthetic process, conservation, and testing has to be carried out under an
43
44 inert atmosphere (N_2) or under vacuum conditions.²⁶ Further analysis with a state-of-the-art
45
46 aberration corrected electron microscope was performed on the one year old sample to confirm
47
48 the presence of PbI_2 monolayers. Figure 2B shows a high resolution HAADF-STEM image of an
49
50 individual PbI_2 nanotube confined within a MWCNT. Due to the tubular nature of the material,
51
52
53
54
55
56
57
58
59
60

1
2
3 brighter lines are observed at the edges indicating a higher density of atoms in the projected
4 image, while the central area presents a lower contrast due to the presence of a hollow cavity.
5
6 The PbI_2 nanotube wall thickness (ca. 0.4 nm), indicated in the figure by orange lines, is in
7 agreement with that of an individual layer of PbI_2 .⁴⁴ Both the curvature and the crystallinity of
8 the structure are well appreciated.
9
10
11
12
13

14
15 In order to provide direct evidence of the superiority of the laser-assisted approach compared
16 to the conventional thermal annealing treatment for the growth of single-walled materials in the
17 interior of CNTs, additional samples were prepared. MWCNT/ PbI_2 mixtures were furnace
18 annealed maintaining the synthesis conditions previously reported for the growth of single-
19 walled PbI_2 within CNTs,¹⁷ and the resulting sample was also analyzed by HAADF-STEM
20 (Figure S7). Visual inspection of the images shows clear differences between the structures
21 grown within MWCNTs by laser irradiation (Figure 2, Figure S2) and conventional thermal
22 annealing (Figure S7). In the case of conventional thermal treatments there is a strong tendency
23 towards the formation of nanowires of PbI_2 (orange arrows), observed as continuous bright bars
24 inside the MWCNTs. On the contrary, the presence of long PbI_2 inorganic nanotubes (green
25 arrows) covering the entire interior of CNTs was predominant when laser treatments were
26 carried out. It is worth noting that when conventional annealing treatments are performed, metal
27 halide nanotubes and nanorods tend to coexist in an individual CNT forming nanotube-nanorod
28 junctions¹⁷ and therefore, metal halide nanotubes above 35 nm in length are already considered
29 as “long” specimens.¹⁸ Remarkably, the majority of single-walled PbI_2 nanotubes prepared by
30 laser irradiation have lengths of hundreds of nanometers.
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50

51
52 HAADF-STEM analyses were performed to quantitatively determine the production yield of
53 single-walled PbI_2 nanotubes. The yield turned out to be more than four times higher when using
54
55
56
57
58
59
60

1
2
3 laser irradiation (ca. 94 % of filled CNTs contained PbI_2 nanotubes; $80 \text{ mJ}\cdot\text{cm}^{-2}$ fluence and
4
5 1000 pulses) compared to conventional thermal annealing (21.7 % of filled CNTs contained PbI_2
6
7 nanotubes). Similar production yields, within experimental error, were observed when
8
9 employing $100 \text{ mJ}\cdot\text{cm}^{-2}$ fluence (1000 pulses). From these analyses it is clear that laser treatment
10
11 leads to the selective formation of high quality single-walled PbI_2 nanotubes, their dimensions
12
13 depending on the length and inner diameter of the hosting carbon nanotubes.
14
15

16
17 It should be remarked that hitherto such selective growth of inner metal halide nanotubes has
18
19 not been obtained through conventional annealing treatments. Actually, using the same annealing
20
21 temperature ($500 \text{ }^\circ\text{C} \pm 25 \text{ }^\circ\text{C}$) a similar yield has been reported for the production of single-
22
23 walled ZnI_2 inside CNTs¹⁸ (21.4 %; $\text{mp}(\text{ZnI}_2) = 446 \text{ }^\circ\text{C}$,⁴² $T_{\text{filling}} = 475 \text{ }^\circ\text{C}$), and even for the
24
25 formation of multi-walled PbI_2 and BiI_3 in the cavities of WS_2 nanotubes⁴⁵ (around 20 % of
26
27 iodide nanotubes; $\text{mp}(\text{PbI}_2) = 410 \text{ }^\circ\text{C}$,⁴² $\text{mp}(\text{BiI}_3) = 408.6 \text{ }^\circ\text{C}$,⁴² $T_{\text{filling}} = 500 \text{ }^\circ\text{C}$). Prolonged 14-30
28
29 days of annealing were employed when using WS_2 nanotubes as templates.^{45, 46} A higher amount
30
31 of single-walled nanotubes within CNTs has been recently reported upon increasing the
32
33 temperature of annealing, from 21.4 % at $475 \text{ }^\circ\text{C}$ to 64.9 % at $1000 \text{ }^\circ\text{C}$, for the van der Waals
34
35 solid ZnI_2 .¹⁸ Nevertheless, not only the production yield is still lower than the one reported here
36
37 (for PbI_2 using laser) but also much longer tubular structures are obtained by laser irradiation.
38
39
40
41

42
43 Considering that the temperature employed for the synthesis of PbI_2 nanotubes by conventional
44
45 annealing ($500 \text{ }^\circ\text{C}$) is considerably lower than the temperature reached by laser irradiation at 80
46
47 $\text{mJ}\cdot\text{cm}^{-2}$ and $100 \text{ mJ}\cdot\text{cm}^{-2}$ ($796 \text{ }^\circ\text{C}$ and $953 \text{ }^\circ\text{C}$ respectively, as per photothermal simulations
48
49 reported in Figure 1), additional thermal treatments of MWCNT/ PbI_2 pellets were carried out at
50
51 these temperatures. Under these conditions the presence of inorganic nanostructures within
52
53
54
55
56
57
58
59
60

1
2
3 MWCNTs was barely observed (Figure S8). Furthermore, the few observed structures did not
4
5 show selectivity towards the formation of inorganic nanotubes.
6

7
8 Raman spectroscopy analyses were performed to determine the quality of MWCNTs' structure
9
10 after laser irradiation. Laser irradiation induces high temperature thermal cycles, which can lead
11
12 to the formation of structural defects, premelting and even amorphisation of MWCNTs.⁴⁷ Raman
13
14 spectra recorded on both non-irradiated and irradiated MWCNT/PbI₂ areas were fitted using four
15
16 Lorentzian and one Gaussian function in the range from 1100-1700 cm⁻¹ (Figure 3, Figure S9).
17
18 The I_D'/I_G ratio was calculated to account for structural variations (Table S1). Despite a slight
19
20 increase in the I_D'/I_G ratio in samples treated with fluences of 80 and 100 mJ·cm⁻², this variation
21
22 does not represent a significant change in the morphology and amount of structural defects of the
23
24 MWCNTs. Therefore, the encapsulation of PbI₂ within the hollow core of MWCNTs is expected
25
26 to take place through the open-ends rather than through structural defects on the MWCNT walls.
27
28
29

30
31 **Mechanism of Formation of Tubular van der Waals Heterostructures.** As mentioned
32
33 above, the laser assisted synthesis is highly selective towards the formation of PbI₂ nanotubes
34
35 with respect to PbI₂ nanowires. Furthermore, when PbI₂ nanotubes are present within the cavities
36
37 of MWCNTs a 100% selectivity towards the formation of single-walled PbI₂ was observed;
38
39 multi-walled PbI₂ were not detected. The reason behind the high selectivity towards the
40
41 formation of monolayered PbI₂ nanotubes with respect to their multi-walled counterparts lies in
42
43 the physico-chemical properties of the template employed (Elicarb[®] MWCNTs) rather than from
44
45 the method employed for their synthesis. In the first report on the growth of PbI₂ nanotubes using
46
47 the conventional thermal annealing method, the formation of multi-walled PbI₂ was also not
48
49 observed.¹⁷ In a more recent study, from over 600 inorganic metal halide nanotubes grown
50
51 within MWCNTs (CeI₃, CeCl₃, TbCl₃ and ZnI₂) only in one case an inorganic nanotube bearing
52
53
54
55
56
57
58
59
60

1
2
3 more than one layer was reported (a triple-walled nanotube of ZnI_2), the rest being single-walled
4
5 (*i.e.* over 99.8 % selectivity).¹⁸ The employed MWCNTs in all these studies have internal
6
7 diameters up to 9 nm, with a larger proportion of nanotubes between 4 and 6 nm.¹⁸ A PbI_2
8
9 monolayer has a larger thickness than atomically thin van der Waals solids such as graphene. As
10
11 a consequence the formation of multi-walled metal halides within the relatively small cavities of
12
13 the MWCNTs employed in this study might not be favored because it would have high strain
14
15 energy. In contrast, the formation of multi-walled metal halide nanotubes has been observed in
16
17 the cavities of WS_2 nanotubes, which have larger diameters.^{45, 46} The diameter of the host is not
18
19 the only parameter that needs to be taken into account when forming tubular core-shell
20
21 heterostructures. For instance, using a semi-empirical model, it was shown that PbI_2 nanotubes
22
23 became stable within the core of MoS_2 nanotubes only above a critical core diameter of the host
24
25 (>12 nm); below this diameter the PbI_2 was found to crystallize as nanowires.⁴⁵ These model
26
27 calculations were in agreement with the experimental observations.⁴⁵ In contrast, when using
28
29 CNTs as templates the formation of PbI_2 nanotubes occurs well below 12 nm.
30
31
32
33
34

35 Molten phase capillary wetting has been suggested as the growth mechanism of a large variety
36
37 of metal halide nanowires inside the cavities of carbon nanotubes, using the methodology that we
38
39 are referring to as “conventional thermal annealing treatment”. Following this approach, PbI_2
40
41 nanowires were grown by Flahaut *et al.* inside the cavities of single-walled and double-walled
42
43 carbon nanotubes back in 2006.⁴⁸ Theoretical calculations on the capillary imbibition of PbI_2
44
45 melt into inorganic and carbon nanotubes suggest that when the ionic melt wets the interior of
46
47 the host nanotube forming a convex meniscus a PbI_2 nanowire will be obtained on cooling,
48
49 whereas when a concave meniscus is created by capillary wetting an inorganic PbI_2 nanotube
50

3 Other mechanisms have been employed for the growth of layered metal halides. Large-scale
4 2D PbI₂ monolayers and few-layers have been recently grown on a SiO₂/Si substrate by a
5 catalyst-free physical vapor deposition process.²⁶ In this case, PbI₂ was added to a ceramic boat
6 and the substrate was placed on top. The furnace was then annealed to 683 K (409.85 °C) at a
7 rate of 24 K/min for short periods of time (1-3 min). Vapor deposition of PbI₂ onto the substrate
8 was observed under these conditions.²⁶ In another study, Tenne *et al.* used electron beam
9 irradiation of a powder of SbI₃ to create tubular core-shell structures using WS₂ as templates.
10 Evaporation followed by recrystallization was suggested as the growth mechanism.⁴⁵

20
21

22 Despite further studies are needed, we reason that the laser irradiation method might favor the
23 vapor deposition of PbI₂ and enhance the formation of PbI₂ nanotubes, whereas capillary wetting
24 would be predominant by the conventional thermal annealing, the latter favoring the formation of
25 nanowires. In fact, molecular dynamic simulations reveal that insertion of molten PbI₂ into CNTs
26 would lead to the formation of PbI₂ nanowires because a convex meniscus is obtained due to the
27 weak wetting of the CNTs by the ionic melt.⁴⁹ Therefore an alternative growth mechanism
28 should be proposed to justify the high yield of single-walled PbI₂ obtained by the laser process.
29 Taking into account that vapor deposition has been employed for the growth of monolayer PbI₂
30 onto a SiO₂/Si substrate at ca. 410 °C,²⁶ it seems plausible that the same growth mechanism takes
31 place during laser processing. Besides, after irradiation of the MWCNT/PbI₂ pellet deposition of
32 PbI₂ is observed on the quartz window of the vacuum chamber, indicating the presence of PbI₂
33 vapor during the process. Nevertheless, molten phase capillary wetting cannot be ruled out since
34 resolidified PbI₂ is also observed in the irradiated areas. After the filling experiment using the
35 conventional thermal annealing, the carbon nanotubes are embedded within resolidified PbI₂,
36 indicating that the carbon nanotubes were in direct contact with the PbI₂ melt during the
37

2
3 annealing step. Therefore, molten phase capillary wetting seems to be favored when using this
4 approach. As mentioned, in the conventional annealing treatment a mixture of CNTs and PbI_2 is
5 placed on one end of a silica ampoule and vacuum-sealed. After the heating step, a slight
6 deposition of PbI_2 is actually observed at the opposite end (cool end during the annealing), far
7 away from the CNTs. Therefore under these experimental conditions vapor deposition would be
8 less favored.
9

10
11
12 **Optoelectronic Properties.** Next, the electronic properties of the prepared materials were
13 investigated. Local resistance characterization of PbI_2 and MWCNT/ PbI_2 pellets irradiated with a
14 laser fluence of $80 \text{ mJ}\cdot\text{cm}^{-2}$ and 1000 accumulated pulses were performed by conducting AFM
15 (Figure 4). Resistance map histograms, presented in Figure 4A, clearly show that a non-
16 irradiated MWCNT/ PbI_2 pellet is less resistive than a pellet of PbI_2 (six orders of magnitude
17 difference in resistance), due to the conducting nature of the MWCNTs. Both, resistance map
18 images (a1 and a2) and corresponding histograms indicate a pronounced decrease on the
19 resistance of the MWCNT/ PbI_2 pellet (blue histogram; average resistance of 3 k Ω) after laser
20 irradiation (red histogram; avg. resistance 1 k Ω). The non-irradiated material consists of a
21 mixture of bulk PbI_2 and empty MWCNTs. The irradiated sample still contains a PbI_2 matrix but
22 the MWCNTs become filled with concentric single-layers of PbI_2 . Therefore, the higher
23 conductivity observed after irradiation could arise from the formed heterostructures of
24 PbI_2 @MWCNTs. This hypothesis was confirmed by analyzing an additional control sample,
25 prepared by irradiating a pellet of bulk PbI_2 under the same laser conditions ($80 \text{ mJ}\cdot\text{cm}^{-2}$ and
26 1000 pulses). Conducting AFM measurements on the irradiated PbI_2 did not present such an
27 increase in conductivity but rather revealed some fading of its resistance. This was probably

7
8 Lead iodide being a light sensitive material and taking into account the interest that van der
9
10 Waals heterostructures of conductive (CNTs) and optically active (PbI_2) materials have for the
11 miniaturization of devices,²⁰ we characterized the optoelectronic response of the material.
12
13 Electrical characterization of laser irradiated MWCNT/ PbI_2 was carried out through current-
14
15 voltage spectroscopy loops in dark conditions and under illumination with a blue light emitting
16
17 diode (LED, ca. 465 nm dominant wavelength). As it can be observed in Figure 4B, the current
18
19 flowing through the material considerably increases upon illumination, accounting for significant
20
21 carrier photogeneration processes. Remarkably this effect was not observed in a pellet of bulk
22
23 PbI_2 where no difference in the conductivity was registered upon illumination. A schematic
24
25 representation of the experimental set-up employed for the conducting AFM measurements is
26
27 presented in Figure 4C. It is worth noting that despite single-walled lead iodide nanotubes are
28
29 protected by the concentric graphene layers of carbon nanotubes, they remain optically active.
30
31 Actually, according to Geim *et al.* each graphene layer is expected to add 2.3 % opacity,⁵⁰
32
33 therefore since the employed CNTs have an average of nine concentric graphene walls (Figure
34
35 S10), about 79.3 % of incident light is expected to reach the inner cavities of the carbon
36
37 nanotubes, where lead iodide is present. Based on DFT calculations a substantial enhancement of
38
39 the visible light response would be expected when interfacing electrically active graphene with
40
41 single-layers of PbI_2 nanosheets.²⁵

49 **Versatility of the Laser-Assisted Filling of Carbon Nanotubes.** To complete the study we
50 investigated whether it was possible to expand the laser-assisted synthesis of tubular van der
51
52 Waals heterostructures to other materials. For this purpose, the same strategy that was employed
53
54
55
56
57
58
59
60

1
2
3 for the formation of PbI_2 @MWCNTs was tested using ZnI_2 as filling material and MWCNTs as
4 hosts. Open-ended MWCNTs were finely ground with zinc iodide powder, and a pellet of 1.3 cm
5 in diameter and ca. 0.5 mm in thickness was prepared by applying a pressure of 10 T to the
6 MWCNT/ ZnI_2 mixture. The pellet was irradiated with an incident laser fluence of $100 \text{ mJ}\cdot\text{cm}^{-2}$
7 using 1000 pulses. The laser-irradiated area was gently scratched and the collected sample was
8 deposited onto a lacey carbon support grid for TEM inspection. As it can be seen in Figure 5,
9 HAADF-STEM imaging confirmed the successful formation of single-walled ZnI_2 nanotubes
10 inside the cavities of MWCNT (see Figure S11 for additional images). The intensity profile
11 acquired along the red arrow (right panel in Figure 5) is in agreement with the presence of a
12 single-walled nanotube. The growth of inorganic nanotubes of ZnI_2 within the cavities of
13 MWCNTs provides evidence of the versatility of the laser-assisted methodology presented
14 herein for the synthesis of tubular van der Waals heterostructures.

33 CONCLUSIONS

34
35 We explored an ultrafast energy efficient methodology for the synthesis of tubular van der
36 Waals heterostructures composed of single-walled lead iodide nanotubes along the inner walls of
37 multi-walled carbon nanotubes. The synthetic strategy, which benefits from fast thermal cycles
38 induced by pulsed laser irradiation, is highly selective towards the growth of single-walled lead
39 iodide nanotubes. This contrasts to previous reports on the encapsulation of van der Waals metal
40 halides into the cavities of CNTs where the formation of nanowires is favored by conventional
41 thermal annealing. It is worth pointing out that whereas core-shell nanostructures of carbon and
42 inorganic materials have been traditionally prepared by filling carbon nanotubes, more recently a
43 complementary synthetic strategy has received widespread attention where previously

1
2
3 synthesized nanowires are covered by a graphene sheet.⁵¹ The laser methodology employed here
4
5 results in the formation of cylindrical van der Waals heterostructures of a conductive (CNT) and
6
7 a light sensitive material (PbI₂), which conductivity can be tuned upon illumination, caused by
8
9 the photogeneration of carriers. The carbon shell offers protection and stability to the monolayers
10
11 of air sensitive lead iodide²⁶ thus allowing its manipulation under ambient conditions.
12
13 Furthermore, since the single-layers of lead iodide easily accommodate to the inner diameter and
14
15 shape of the CNTs, it should allow strain engineering of van der Waals solids. It is well
16
17 established that the properties of single-layered crystals can be tuned by inducing strain, for
18
19 instance upon bending.⁶ Versatility of the laser-assisted synthesis was confirmed by growing
20
21 single-walled ZnI₂ within MWCNTs. We believe that the use of laser irradiation, which is widely
22
23 employed in industrial processes, will allow the encapsulation of a large variety of materials into
24
25 CNTs including for the formation of van der Waals heterostructures in a simple, fast, and energy
26
27 efficient manner.

34

35 METHODS

36
37 **MWCNTs Purification.** MWCNTs (CVD, Thomas Swan & Co. Ltd.) were firstly steam
38
39 purified to remove amorphous carbon and catalyst nanoparticles, as previously reported.⁵² This
40
41 procedure involves placing MWCNTs in a furnace at 900 °C for 5 h with a constant flow of
42
43 steam/argon mixture. Being a mild oxidizer, steam oxidizes graphitic shell around catalyst
44
45 nanoparticles and opens the nanotubes' ends. Subsequently, the sample was placed into a round-
46
47 bottom flask and refluxed with 6 M HCl at 110 °C for 6 h to remove the catalyst particles, cooled
48
49 down and filtered through 0.2 μm polycarbonate membrane filters, washing with distilled water
50
51 until neutral pH was reached and dried.
52
53
54
55
56
57
58
59
60

1
2
3 **Laser-assisted Synthesis of PbI₂ Nanotubes.** 36 mg of purified MWCNTs were mixed with
4
5 210 mg of PbI₂ (Strem Chemicals Inc.) and well homogenized using an agate pestle and mortar
6
7 inside an argon-filled glovebox. Pellets with 1.3 cm in diameter and ca. 0.5 mm in thickness
8
9 were formed applying a pressure of 10 T to the MWCNT/PbI₂ mixture. An additional pellet
10
11 containing 260 mg of PbI₂ was prepared to be employed as a reference.
12
13

14
15 Pulsed laser treatments of MWCNT/PbI₂ pellets were carried out by means of a Nd:YAG laser
16
17 system (266 nm, 3 ns pulse duration, 10 Hz pulse repetition rate; Brilliant model from Quantel).
18
19 The experiments were performed inside a vacuum chamber at a pressure of 10⁻⁴ Pa to avoid
20
21 oxidation reactions. A quartz window was placed on top of the pellet to prevent direct deposition
22
23 of PbI₂ onto the optical window of the vacuum chamber. The irradiations were done by focusing
24
25 the laser beam onto the sample surface, creating 1×1 mm² homogeneous squared spots. The
26
27 distance between two adjacent irradiated spots was set to be 1 mm. Different samples were
28
29 obtained by accumulation of 10, 100 and 1000 subsequent laser pulses per site with an incident
30
31 laser fluence of 40, 60, 80 and 100 mJ·cm⁻². Two additional samples were prepared using 10000
32
33 pulses (100 mJ·cm⁻²) and 200 mJ·cm⁻² (1000 pulses).
34
35
36
37

38 **Synthesis of PbI₂ Single-walled Nanotubes by Thermal Treatment.** Steam purified and HCl
39
40 treated MWCNTs (6 mg) and PbI₂ (140 mg) were ground together with an agate mortar in a free
41
42 oxidant atmosphere and placed into a silica ampoule, evacuated and sealed under vacuum.
43
44 Afterward, the sample was annealed employing a 5 °C·min⁻¹ heating rate, dwelled at 500 °C for
45
46 12 h and cooled to room temperature. Additional samples were prepared by annealing
47
48 MWCNT/PbI₂ pellets, prepared as detailed above for the laser assisted synthesis, at 796 °C and
49
50 953 °C.
51
52
53
54
55
56
57
58
59
60

1
2
3 **Laser-assisted Synthesis of ZnI₂ Nanotubes.** 9 mg of purified MWCNTs were mixed with
4
5 300 mg of ZnI₂ (Sigma-Aldrich) and well homogenized using an agate pestle and mortar inside
6
7 an argon-filled glovebox. Pellets with 1.3 cm in diameter and ca. 0.5 mm in thickness were
8
9 formed applying a pressure of 10 T to the MWCNT/ZnI₂ mixture. The pellet was irradiated as
10
11 described above for PbI₂.
12
13

14 **Sample Characterization.** Spots were characterized by Raman spectroscopy (Horiba Jobin
15
16 Yvon) operating at 532 nm and using 100× objective. Acquisition time was set to 30 s and laser
17
18 power to 0.5 mW. Spectra were obtained from several random places at each irradiated spot and
19
20 fitted using OriginPro 8 software. Scanning electron microscopy characterization was performed
21
22 on an FEI Magellan 400L at 5 kV, using a through-lens (TLD) detector for secondary electrons
23
24 acquisition and a vCD detector optimized for high-contrast backscattered detection at low kV.
25
26 Additionally the morphology of the irradiated spots was evaluated using high-angle annular dark
27
28 field (HAADF) imaging in high resolution scanning transmission electron microscopy (STEM),
29
30 carried out in a FEI Tecnai G2 F20 microscope operating at 200 kV. Samples were prepared by
31
32 placing dropwise onto a lacey carbon support grid the dispersion obtained after sonication of a
33
34 scratched fraction of the laser-irradiated area in hexane. Films morphology and resistance at the
35
36 sub-micron scale was characterized by atomic force microscopy (AFM) using a 5500LS system
37
38 from Agilent Technologies equipped with a Resiscope II module (CSI Instruments). Resistance
39
40 maps were acquired in contact mode using diamond-coated silicon tips with a diameter of about
41
42 100 nm. The resistance maps were acquired by applying 1 V between tip and sample. Current-
43
44 voltage (I-V) spectroscopy analyses were also performed at specific locations of the samples by
45
46 measuring the current flow through the tip in contact with the samples' surface while ranging the
