ABSTRACT

2
3 The mechanisms translating global circulation changes into rapid abrupt shifts in forest carbon
4 capture in semi-arid biomes remain poorly understood. Here we report unprecedented
5 multidecadal shifts in forest carbon uptake in semi-arid Mediterranean pine forests in Spain over
6 1950-2012. The averaged carbon sink reduction varies between 31-37%, and reaches values in the
7 range of 50% in the most affected forest stands. Regime shifts in forest carbon uptake are
8 associated with climatic early warning signals, decreased forest regional synchrony, and reduced
9 long-term carbon sink resilience. We identify the mechanisms linked to ocean multidecadal
10 variability that shape regime shifts in carbon capture. Firstly, we show that low frequency
11 variations of the surface temperature of the Atlantic Ocean induce shifts in the non-stationary
12 effects of El Niño Southern Oscillation (ENSO) on regional forest carbon capture. Modelling
13 evidence supports that the non-stationary effects of ENSO can be propagated from tropical areas
14 to semi-arid Mediterranean biomes through atmospheric wave trains. Secondly, decadal changes
15 of the Atlantic Multidecadal Oscillation (AMO) significantly alter sea-air heat exchanges,
16 modifying in turn ocean vapour transport over land and land surface temperatures, and promoting
17 sustained drought conditions in spring and summer that reduce forest carbon uptake. Thirdly, we
18 show that lagged effects of AMO on the winter North Atlantic Oscillation (NAO) also contribute
19 to the maintenance of long-term droughts. Finally, we show that the reported strong, negative
20 effects of ocean surface temperature (AMO) on forest carbon uptake in the last decades are
21 unprecedented over the last 150 years. Our results provide new, unreported explanations for
22 carbon uptake shifts in these drought-prone forests and review the expected impacts of global
23 warming on the profiled mechanisms.
24

Introduction

2 The quest to identify the diverse mechanisms driving abrupt shifts in the dynamics of climate
affecting ecosystems has gained considerable scientific attention in recent decades (Lenton *et al.*
4 2008, Scheffer *et al.* 2009). Numerous empirical studies have reported abrupt regime shifts
between contrasting persistent states of these ecosystems (Scheffer *et al.* 2009, Chen & Tung
6 2014). Several natural phenomena have been long identified as key drivers of rapid changes in the
state of terrestrial ecosystems and in their carbon sink capacity, including changes in regional
8 climate regimes. Multidecadal fluctuations in sea surface temperatures (SST), quantified by ocean
variability indices (e.g. the Atlantic Multidecadal Oscillation (AMO), and the Pacific Decadal
10 Oscillation (PDO)), are important drivers of long-term changes in the trends of rainfall in tropical,
semi-arid and extratropical areas of the globe (McCabe *et al.* 2004, Sutton & Hodson 2005). Rapid
12 shifts in SST can affect multiple ocean basins, forcing regime shifts in global atmospheric
circulation patterns (Quan *et al.* 2004, Wang *et al.* 2013). Changes in SSTs also control inter-
14 annual variability in the global terrestrial sink, through the propagation of temperature and rainfall
anomalies (Bastos *et al.* 2013, Poulter *et al.* 2014, Kim *et al.* 2017). However, the precise
16 mechanisms connecting major changes in the thermal state of ocean basins and the carbon sink
dynamics of forest ecosystems remain yet poorly understood. For example, we lack
18 comprehensive descriptions of the multiple mechanisms linking long-term carbon sequestration by
forests to multidecadal shifts in SSTs. Similarly, it has not been assessed whether transitions
20 between the warm and cold ocean phases result in abrupt or gradual shifts in forest carbon uptake
regimes, whether and how these shifts vary geographically and the diverse climatic mechanisms
22 implied.

Recent research indicates that semi-arid forests are key determinants of the variability in the
24 carbon sink capacity of terrestrial ecosystems (Poulter *et al.* 2014). Semi-arid and dryland systems
cover 45% of the Earth's land surface, and recent assessments assert that over the last decades are

2 becoming an increasingly important driver of the terrestrial carbon sink capacity of the Earth at
interannual time scales (Poulter *et al.* 2014, Ahlström *et al.* 2015). These biomes are distributed at
the transitional edge between desert and temperate regions of the biosphere, and as a result their
carbon sink activity could be severely disrupted during the next decades by global warming and
the ongoing latitudinal expansion of the Hadley cells (Fu 2015, Lau & Kim 2015). In addition,
global warming may possibly induce an increased frequency and severity of eastward propagating
extreme El Niño events, and impact drought regimes in key semi-arid areas (Cai *et al.* 2015).

8 Here we examine the occurrence of regime shifts in forest carbon uptake in the dominant dry
coniferous forests of the Western Mediterranean Basin (Aleppo pine, *Pinus halepensis* Mill.),
located in continental Spain. Detailed empirical descriptions of regime shifts in forest carbon
uptake are currently lacking in this semi-arid region. Next, we provide empirical evidence for
several mechanisms driving regime shifts in forest carbon uptake. The first mechanism examined
is the operation of large-scale, non-stationary effects of El Niño Southern Oscillation (ENSO)
events that are propagated from tropical to extratropical areas through atmospheric wave trains
(López-Parages & Rodríguez-Fonseca 2012, López-Parages *et al.* 2015, 2016). The ENSO is the
strongest year-to-year climate fluctuation of the planet and it is tightly linked to interannual
variations in carbon sink capacity of terrestrial ecosystems (Hashimoto *et al.* 2004). The
propagation of the ENSO signal from tropical to extratropical areas can be strongly modulated by
ocean multidecadal variability and this has not been considered in the analysis of forest carbon
uptake regime shifts. To address this gap here we analyse how the interactions between the ENSO
and the Atlantic Ocean Multidecadal Oscillation (AMO) could jointly drive regime shifts in forest
carbon uptake. The second mechanism examines the effects of ocean multidecadal variability in
SST on long-term trends of sea-air heat exchange, water vapour transport over land, sea level
pressure and land temperature conditions. Changes in these climatic variables linked to ocean
multidecadal states can induce sustained drought conditions over land and limit the carbon sink

capacity of forests. Thirdly, we analyse whether lagged multidecadal variability in major
2 atmospheric modes such as the North Atlantic Oscillation (NAO) significantly affects long-term
drought events. The positive phase of AMO results in more frequent negative NAO events and
4 blocking episodes associated to extreme climate events (Häkkinen *et al.* 2011, Peings &
Magnusdottir 2014). Moreover, lagged multidecadal links between AMO and NAO have been
6 extensively documented, and may influence drought events and therefore forest ability to uptake
carbon (Peings & Magnusdottir 2014, Li *et al.* 2013).

8 To summarise, here we address the following research objectives: *i*) to provide a first description
of coupled shifts in drought regimes and carbon uptake in semi-arid Aleppo pine forests in Spain,
10 using combined climatic and dendrochronological time-series analyses spanning the last six
decades (1950-2012); *ii*) to characterize the observed regime shifts using diverse statistical
12 techniques including early-warning signal analyses; *iii*) to identify the teleconnections
significantly associated with the reported regime shifts, quantifying the associated changes in the
14 patterns of ocean water vapour transport over land, land temperature and sea level pressure; *iv*) to
test whether the non-stationary effects of ENSO mediated by ocean multidecadal variability
16 determine the onset of regime shifts of forest carbon uptake; and *v*) to provide a unified framework
for all the examined mechanisms, summarising the expected effects of global warming on the
18 studied processes.

Materials and Methods

Climatic and forest data

20 The study area comprised the Spanish Iberian Peninsula and it was subdivided into grids of
22 280×280, 140×140, and 70×70 km² (Supplementary Fig. 1). Climatic data were obtained from the
State Meteorology Agency (AEMET) during 1950-2012. We used the Standardised Precipitation
24 Evapotranspiration Index (SPEI) to quantify droughts (Vicente-Serrano *et al.* 2010). A spatially

averaged value of monthly SPEI was calculated for each grid cell during the 1950-2012 period.

The resulting data set was structured in a pool of 5191 SPEI grids, covering different time scales

(3, 6, 9, 12, 18, 24, and 36 months; Domingo-Marimón 2016). Monthly values of sea-level

pressure (SLP), water vapor transport and temperature fields between 1950 to 2010 at 1 degree

resolution were derived from ERA-20C Reanalysis (Poli *et al.* 2016). The yearly variation in gain

of carbon stocks was quantified in a network of 20 Aleppo pine forests (*Pinus halepensis* Mill.)

(Supplementary Fig. 1). Dendrochronological analyses and allometric equations were applied to

calculate the variation in carbon stocks linked to tree growth in each of the forest stands for 1950-

2012 ($\text{kg ha}^{-1} \text{y}^{-1}$, Forest net carbon uptake hereafter [*FCU*], Montero *et al.* 2005). Note that this

variable does not account for tree and soil respiration fluxes and therefore provides a proxy of the

net primary productivity specifically linked to tree growth (Montero *et al.* 2005). Tree density and

stand basal area were measured in each stand (Ribas, 2006, Camarero *et al.* 2015a). A variable

number of trees (8-38) were randomly sampled for dendrochronological analyses in an area of 2 ha

(Ribas, 2006). The selected trees were located at least 5-10 m apart. We extracted 2-4 radial cores

per tree at 1.3 m using a Pressler increment borer. Wood samples were sanded and visually cross-

dated. Tree-ring widths were measured to the nearest 0.01 mm using a LINTAB measuring device

(F. Rinntech, Germany), a binocular scope, and the programmes CATRAS and TSAP. The

COFECHA software was used to assess the accuracy of the visually cross-dated samples. For each

tree, we also measured the diameter at breast height (DBH, measured at 1.3 m), the stem height

and the bark thickness to calculate the annual increase in basal area.

Description of regime shifts

We first assessed the existence of unreported abrupt shifts in drought regimes and forest carbon

uptake, analysing the time series of drought trends and dendrochronology data in the Iberian

Peninsula (*objective i*). The SPEI allowed us to explore shifts in drought regimes at temporal

scales ranging from 3 to 36 months during 1950-2012. SPEI and dendrochronological time series

were analyzed applying spline fits (SAS Institute 2012). To assess the effects of abrupt shifts in the drought regime on forest carbon storage, we subsequently examined the yearly increase in carbon stock in a large-scale network of 20 Aleppo pine forests during 1950-2012 (Supplementary Figure 1). This tree species was selected because it is the dominant native conifer in the eastern Iberian Peninsula and in the driest areas of the Western Mediterranean Basin. The selected stands represented the native geographical distribution of this taxon across the Iberian Peninsula, providing a regional assessment for this species (Supplementary Fig. 1). Regression tree analyses were applied to detect abrupt shifts in time series (De'ath & Fabricius 2000). We identified an optimal splitting point (i.e. time of shift) in the time series separating multiannual periods characterized by contrasting values in the analysed variable. The magnitude of the shift between two periods was quantified by the amount of the variance explained by the model and was therefore inversely proportional to the model-corrected Akaike Information Criterion (1/AICc). The splitting criterion was based on the LogWorth statistic (SAS Institute 2012). When a significant shift was detected in the regression tree and spline analyses, we applied a Tukey-Kramer analysis to test for significant differences in values between the two multiannual periods before and after the splitting point. For all forest stands, we computed the resistance, recovery and resilience indices for tree growth and analysed their trends (LLoret et al. 2011, Gazol et al. 2018). In addition, these indices were subsequently modified in a second step to more properly describe decadal trends. We computed the following indices of forest resilience (FCUR) and recovery capacity after a regime shift (FCURC), defined as follows:

$$FCUR = \frac{\bar{X}_{FCU \text{ BEFORE } (5 \text{ years})}}{\bar{X}_{FCU \text{ AFTER } (t \text{ years})}}$$

where \bar{X}_{FCU} is the averaged forest net carbon uptake ($\text{kg ha}^{-1} \text{ y}^{-1}$) over a 5 year period *before* the regime shift in the numerator and over a variable number years *after* the regime shift in the

denominator (t , ranging from 1 to 30 years). The recovery capacity after a regime shift was
2 computed as follows:

$$FCURC = \frac{FCU_{AFTER}(\text{year of the shift})}{\bar{X}_{FCU_{AFTER}(3\text{ year rolling window})}} - 1$$

4 Finally, following previous works (Camarero et al. 2015a) we also computed a synchronicity
index, measured as the averaged *Pearson r* coefficient between the forests stands.

6 *Early-warning signal analyses*

To characterise early-warning signals associated to the observed regime shifts, early-warning
8 signals were quantified using the *earlywarnings* R package (Dakos et al. 2012) using climatic data
(*objective ii*). The analyses were restricted to the time period before the splitting point previously
10 identified by the regression tree models. The functions *generic_ews* and *qda_ews* were used to
estimate the following eight statistical moments within rolling windows along the time series: the
12 autoregressive coefficient [ar(1)] of a first-order AR model fitted to the data, the standard
deviation, skewness, kurtosis, the coefficient of variation, the return rate of the data estimated as
14 the 1-ar(1) coefficient, the density ratio of the power spectrum of the data estimated as the ratio of
low to high frequencies, and the autocorrelation at the first lag of the data (Supplementary Table
16 1). The trends of these eight statistical moments were estimated by using the nonparametric
Kendall tau correlation coefficient. The function *sensitivity_ews* was applied to plot the Kendall
18 tau estimates and their *p*-values for the range of rolling-window sizes used, together with a
histogram of the distributions of the statistic and its significance. The analyses were computed for
20 a large range of window sizes (winsize parameter: 10, 20, ...50). We computed and plotted the
power spectrum estimated by the *spec.ar* function for all frequencies within each rolling window.
22 Positive feedback processes originating non-linear responses and early warning signals may occur
in both climatic and ecological processes (Supplementary Fig. 2). Consequently, early-warning

signals were assessed for climatic and forest variables (SPEI 3-12; FCU variables) and contrasted applying Tukey-Kramer tests.

Teleconnection analyses

To analyse the effects of teleconnections on drought and carbon uptake regime shifts (*objective iii*), we gathered data for the following teleconnection indices: the AMO, the Multivariate ENSO index (MEI), the North Atlantic Oscillation index (NAO), the Western Mediterranean Oscillation index (WeMOI), and the Arctic Oscillation (AO) index, the Pacific Decadal Oscillation (PDO) and the Eastern Atlantic Pattern (EA) (see supplementary materials for further details on data sources). Structural equation models (SEM) were applied to assess the relative influence of teleconnection indices on SPEI variability (*objective iii*) (R Development Core Team 2017). Alternative SEM models were compared and selected minimizing the AIC and the Bayesian Information Criterion (BIC). The basic SEM model scheme selected is outlined in Supplementary Fig. 3. SEM models were complemented with multiple regression analyses (based on Ordinary Least Squares, OLS). Linear regression analyses of teleconnection indices were performed for SLP, water vapor transport, SPEI and mean air surface temperature to map the effects of teleconnection indices on atmospheric circulation patterns. Wavelet coherence analyses allowed the detection of similar periodicities in the fluctuations of teleconnection and SPEI time series and the estimation of their phase differences.

Regime shifts and non-stationary interactions between ENSO and AMO

We hypothesized that the multidecadal variation of the Atlantic SST measured by the AMO could trigger regime shifts in drought and, as a consequence, in net forest carbon capture linked to tree growth (FCU). The proposed mechanism is the operation of non-stationary effects of higher frequency teleconnection patterns (e.g. ENSO and other teleconnection indices) modulated by ocean multidecadal variation (López-Parages & Rodríguez-Fonseca 2012, López-Parages *et al.*

2015, 2016). To assess whether non-stationary effects of ENSO mediated by ocean multidecadal variability (AMO) were determining the onset of regime shifts in drought and carbon uptake trends (*objective iv*) we tested two diagnostic predictions. Firstly, we documented the occurrence of spatiotemporal shifts in the non-stationary effects of MEI on drought (SPEI) (*Prediction 1, P1*). To test this prediction, we performed multiple regression modelling analyses (ordinary least squares, OLS) for subsets of consecutive 10-year time windows for each grid cell in the study region, allowing the detection and mapping of non-stationary effects of ENSO. Complementarily, we also assessed the non-stationary effects observed for other teleconnections characterised by high frequency, interannual variability modes (NAO, WeMOI, EA, AO). Significant multiple regression estimates of the OLS models were subsequently mapped for each decade allowing the detection of spatial and temporal shifts in the effects of ENSO, NAO and high-frequency teleconnections on SPEI. Secondly, we analyzed whether rapid changes in the AMO during the regime shift period significantly predicted the changes in the non-stationary effects of the Multivariate ENSO index on net forest carbon capture associated with tree growth (*FCU*) (*Prediction 2, P2*). To assess this prediction, we performed rolling correlation analyses between forest carbon uptake (*FCU*, $\text{kg ha}^{-1} \text{y}^{-1}$) and the MEI index [*rFCU-MEI* correlation coefficients hereafter]. Rolling correlation analyses were calculated for each forest stand using the *rollaplyr* function in the package *zoo* (R Development Core Team 2017), obtaining the Pearson correlation coefficient in the *cor* function (*stats* package) and running the analyses for varying window width parameters (10, 15, 20, 25 years). The analyses of *rFCU-MEI* correlation coefficients were conducted for annual and monthly values of MEI. Furthermore, we analysed whether the AMO was significantly associated with the variation observed in the *rFCU-MEI* correlation coefficients. During regime shifts, we expected the observation of significantly negative relationships linking *rFCU-MEI* values and the AMO index, due to increased negative effects of ENSO on forest carbon uptake associated with a warmer AMO state.

Testing for amplified effects of AMO during the last 150 years

2 To analyse whether the reported negative effects of AMO on forest carbon uptake detected in
1950-2012 were unprecedented during the last 150 years, we extended the analyses to the 1850-
4 2012 time period. We applied ordinary squares multiple regression models (OLS) analysing the
effects of teleconnection indices on forest carbon uptake. The OLS models contrasted the observed
6 effects of AMO on forest carbon capture for different consecutive time periods over the 1850-
2012 series, and were repeated at different time period resolutions (decadal, bidecadal, 30 years
8 [corresponding to AMO positive and negative periods], 60 years). For the 60-year resolution, we
computed the observed AMO effects in the IPCC-AR5 reference period (1850-1899, P1) and in
10 two subsequent time periods (P2: 1900-1959 and P3: 1960-2012). Changes in the starting year of
the analysed multidecadal periods did not qualitatively change the reported results. Results for
12 decadal and bidecadal resolution are not shown.

Testing complementary hypotheses

14 Forest carbon uptake trends can be significantly affected by stand structure and past management
practices (Pan *et al.* 2011, Coomes *et al.* 2014), by tree age, height and ontogenetic stage
16 (Camarero *et al.* 2015b) and by the increase of post-industrial atmospheric CO_2 concentrations
(Camarero *et al.* 2015b, Keenan *et al.* 2016). To assess the effects of these complementary
18 processes on the reported trends of forest carbon uptake the following variables were quantified:
stand tree density, stand mean diameter at breast height, stand mean tree height, the age of the
20 sampled trees, and the annual increase of atmospheric concentrations of CO_2 (see supplementary
Table S2 for a detailed description). Following the methods proposed in previous works
22 (Camarero *et al.* 2015b), we extracted the residual variation of forest carbon uptake not linked
forest structure and age ($resC_{incr}$). Subsequently, we tested whether this remaining variation was

significantly associated to the examined teleconnections (AMO, MEI, AO, WeMOI, NAO) and to the variation of post-industrial atmospheric CO₂ applying multiple regression OLS analyses.

Results

Drought and forest carbon uptake regime shifts (objective i)

Regression tree analyses identified a consistent shift in SPEI trends affecting the entire central-eastern Iberian Peninsula in 1980-1981 (Fig. 1). This abrupt shift was characterised by drier conditions from the 1980s onwards, and it was consistently detected in regression tree models across a wide range of SPEI temporal scales (3-36 months) and across different scales of spatial grids (Supplementary Figs. 4-8). Average SPEI values consistently differed before (1950-1979) and after the abrupt shift (Supplementary Fig. 9a, Tukey-Kramer test $p < 0.0001$). A different pattern of longitudinal variation of average SPEI values was observed before and after the 1980-1981 shift – with the SPEI switching from increasing with longitude to decreasing with longitude, i.e. climate conditions were drier eastwards (towards the Mediterranean coast) after the shift (Supplementary Fig. 9b).

As found for SPEI, the trends in carbon stocks clearly shifted in 1980-1981 in 18 of the 20 forests, changing from sustained positive gains to stable, non-significant trends (Fig. 2a, Supplementary Figs. 10-12). The trends in two cases reversed from significantly positive to significantly negative (Fig. 2a). Regression tree models based on the changes in forest carbon uptake identified significant shifts in 16 of 18 stands during 1978-1981 (Supplementary Table 3), in line with the shift in drought dynamics (Fig. 1). Before the regime shift, we observed a progressive significant increase in forest carbon uptake synchrony (Fig 2b, cubic polynomial fit, $p < 0.0001$), followed by a significant reduction after the shift ($p < 0.0001$, Supplementary Figure S13). For the whole period after the regime shift, synchrony values remained significantly lower relative to 1950-79 (T-K test, $p < 0.0001$) and there was an increase of non-significant values

(Supplementary Fig. S13). In a similar manner, the forest carbon uptake resilience index (FCUR) indicated a sustained reduction (31 - 37%) of the forest sink after the regime shift (Fig 2b, see Supplementary Table 4 for further details). Forests were also characterised by a limited recovery capacity, with most stands showing recovery rates of 10-17% respect to the minimum FCU level observed after the drought regime shift (Fig 2c, Supplementary table 5). In summary, all the results indicated a coherent abrupt large-scale shift in forest carbon uptake trends in this area and allowed testing for alternative large-scale drivers of these trends.

Early-warning signal analyses (objective ii)

Having identified abrupt shifts in forest and drought regimes, we examined whether they carried any early-warning signals. We assessed this by estimating changes in lag-1 autocorrelation in the time series before the regime shift (Dakos et al., 2012, Camarero et al., 2015a). Abrupt shifts in drought regime in the eastern Iberian Peninsula were preceded by an increase in autocorrelation only in SPEI (Fig 3a, Supplementary Fig. 14). In contrast, non-significant AR-1 values were observed in FCU time series before the shift (Fig 3a). In line with these findings, SPEI AR-1 and the Kendall tau statistic quantifying autocorrelation trends were positively associated with the magnitude of the regime shift in the local SPEI time series (Fig. 3b, c). In other words, sites experiencing more abrupt shifts in SPEI values in 1980 (i.e. presenting higher values of R^2 and $1/AIC$ in regression tree models) showed significantly higher Kendall tau and AR-1 values before the regime shift (i.e. in 1970-79). Overall, all the early-warning results indicated a major role of climatic variables as putative drivers of the reported shifts, highlighting the need of detailed analyses of teleconnections and climatic variables.

2 *Teleconnections associated with the reported regime shifts (objective iii)*

3 The models identified AMO as the strongest predictor of the variability in SPEI values (Fig. 3d,
4 Supplementary Fig. 15, and Supplementary Table 6). Furthermore, the standardised coefficients of
5 AMO on SPEI were robust predictors of the magnitude of the regime shift detected by the
6 regression tree models in each grid cell (Fig. 3e). In addition, wavelet coherence analyses
7 confirmed the observed significant links between the AMO index and the SPEI values, reporting
8 significant associations at long time periods (>128 months) in cells characterised by strong shifts
9 in drought regime (Supplementary Fig. 16). These results identified the AMO index as a
10 significant predictor of the abrupt shifts in the drought regimes (Supplementary Table 6).
11 Moreover, the values of the Kendall tau statistic quantifying autocorrelation trends were positively
12 associated with the effect of the AMO on the drought indices (Fig. 3f). In the case of tree carbon
13 sequestration models, we applied multiple regression OLS models and identified AMO as the best
14 teleconnection index for predicting changes in carbon stocks in the Aleppo pine stands. The
15 models revealed a significantly stronger AMO signal for carbon-stock gains in northern stands
16 (Supplementary Table 7).

17 In order to understand the physical processes driving the correlations found, we applied regression
18 analyses mapping the effects of AMO on ocean and land water vapour transport, sea level
19 pressure, ocean surface temperature and land mean air temperature (Supplementary Fig. 17, see
20 Methods). Positive AMO states were significantly associated with increased drought conditions
21 across the Iberian Peninsula, spanning from January to October (Supplementary Fig. 17).

22 Furthermore, analyses of the seasonal variation of SPEI after the regime shift reported a significant
23 increase of drought impacts in the same seasonal time period (winter, spring and summer), which
24 were in turn paralleled by a significant increase of AMO positive anomalies in spring and summer

(Supplementary Fig. 18). Thus, changes in the annual dynamics of AMO and SPEI largely impacted the growing season of forests.

Regime shifts and non-stationary interactions between ENSO and AMO (objective iv)

The results suggested a key role of non-stationary effects of ENSO modulated by AMO and supported the two diagnostic predictions (*P1* and *P2*). Firstly, multiple regression OLS models for the SPEI drought index for subsets of consecutive 10-year time windows allowed the detection of non-stationary effects of higher frequency teleconnections. The models detected changes in the non-stationary effects of the El Niño Southern Oscillation (MEI), promoting autumn rains in the 1970s and increased spring and summer drought conditions during the start of the regime shift, in the 1980s (Fig. 4a), being the former more marked in the south and western part of the Iberian Peninsula and the latter in the south and eastern part. Crucially, the spatial shifts in the effects of the models in the 1980s closely matched the spatial pattern reported for the drought patterns (Fig. 1). The models also highlighted a key role of non-stationary effects of positive winter NAO phases (December, January) in the 1990s, showing a multidecadal pattern (Fig 4b). Of note, the NAO signal was significantly correlated with lagged AMO, and this correlation was maximised at a lag of 15 years ($R^2=0.16$; $p=0.0048$), as reported in previous works (Li et al. 2013). In addition, we examined whether AMO was a significant predictor of the correlations between forest carbon uptake and ENSO ($rFCU-MEI$ correlations) during the onset of the regime shift period (1980s). As predicted, in the 1980s we observed a significantly negative $rFCU-MEI / AMO$ relationship in the stands affected by regime shifts (Fig. 5a). A shift to a warmer state of the AMO index in the 1980s was consistently associated to more negative Pearson correlation values, and the observed negative relationships were mostly significant from March to October (Fig. 5b-c). The analyses covering the 1850-2012 period reported that the strong, negative effects of AMO in the 1980s were unprecedented over the last ~150 years (Supplementary Fig. S19, and Supplementary Table 8). While previous negative AMO phases [e.g. 1897-1930] were significantly associated to increased

forest carbon uptake levels in the OLS models (Supplementary Table 8), strong linear effects of AMO were only detected in the regime shift period (i.e. in the 1980s [1963-1996 negative AMO phase], see Supplementary Fig. S19).

Effects of forest stand structure, tree age and atmospheric CO₂

We observed that forest tree density, mean stand tree height and tree age explained a significant fraction of forest carbon uptake variation across sites ($R^2=0.27$; $p<0.0001$, Supplementary Table 10). OLS models examining the residual variation after accounting for stand structure and tree age effects indicated that the reported effects of AMO were robust (Supplementary Table 11).

Similarly, the results indicated a significant but small effect of increased atmospheric CO₂ concentrations on forest carbon uptake, which co-acted with significant negative effects of AMO (Supplementary Table 12).

Discussion

Our results describe previously unreported regime shifts in drought and carbon uptake across Iberian Aleppo pine forests (Figs. 1-2), and identify the climatic drivers implied (Figs. 3-6). This tree species is the most dominant conifer in semi-arid or dry lowland areas of the Western Mediterranean Basin and therefore it is of major ecological relevance in such drought-prone regions. The reported drought regime shifts strongly affect forest carbon uptake of these forests, showing a sustained multidecadal reduction of carbon sequestration. The averaged carbon sink reduction for all stands varies between 31-37%, but reaches values in the range of 50% in the most affected stands (Fig 2b). SEM analyses indicated that AMO is the key regulator of the observed trends, being in turn significantly associated to early warning indicators. The results indicate that AMO acts as a key modulator of different non-stationary mechanisms over analysed drought regime shift period. We suggest that the mechanisms operate sequentially, following this order: 1) the modulation by AMO of the effects of ENSO on drought and forest carbon uptake, acting over

the 1970s-1980s (e.g. Figs. 4 and 5), which is a key mechanism because it determines the onset of the regime shift period; 2) a sustained negative effect of positive AMO phases on ocean moisture advection and water transport at the multidecadal scale, acting over the 1980s-2000s, and linked to a significant increase on spring and summer temperatures (Supplementary Fig. 17); and, lastly, 3) the lagged multidecadal variation of the NAO (relative to the AMO) that significantly affects drought indices in the 1990s. A synthetic diagram summarising these three mechanisms is provided in Fig. 6.

Referring to the first mechanism, our results support that non-stationary interactions between ocean multidecadal variability (AMO) and the ENSO determine the onset of abrupt shifts in forest carbon capture in the studied semi-arid forests. We propose that these non-stationary effects of ENSO in extratropical areas could be possibly linked to modified Rossby wave train activity (López-Parages & Rodríguez-Fonseca 2012, López-Parages *et al.* 2015, 2016) (e.g. Supplementary Fig. 20). The abrupt, non-linear regime shift observed in the 1980s and its significant association with both AMO and ENSO suggest a key role for non-linear atmospheric responses specifically linked to the patterns of sea surface temperature (SST) associated with ENSO and AMO. Below, we review in detail the fundamental processes that may shape this mechanism.

It is well known that AMO and ENSO describe large-scale patterns of SST and therefore influence air-sea heat exchanges. Increases in SST induce a net transfer of heat from the sea to the atmosphere and result in diabatic heating of the lower atmosphere (Bjerknes 1964, Gulev *et al.* 2013). Through these diabatic processes SST can in turn influence ocean-land advection and zonal winds, as well as the dynamics of the Walker and Hadley circulation cells (Wang 2002, Sutton and Dong 2012). All these fundamental air-sea exchanges may upscale affecting large geographic regions, modifying in this way atmospheric circulation dynamics and Rossby wave train dynamics, and shifting the geographic location of anticyclones and lows (Cassou *et al.* 2005,

López-Parages & Rodríguez-Fonseca 2012, Mariotti *et al.* 2012, López-Parages *et al.* 2015, 2016,
2 Sun *et al.* 2017).

Previous works have shown that above determinate threshold values of SSTs non-linear trends in
4 atmospheric responses and rainfall patterns have been consistently observed (Quan *et al.* 2004,
Power *et al.* 2006, López-Parages *et al.* 2016). Crucially, the available evidence supports that
6 atmospheric Rossby wave trains can respond non-linearly to changes in ocean thermal state (SST)
and to ENSO events (Hoerling *et al.* 2001, López-Parages *et al.* 2016). In other words, non-linear
8 atmospheric effects linked to increased SST can shape Rossby wave train activity connecting
major ocean basins and strongly affect rainfall trends in extratropical areas as the Iberian
10 Peninsula (López-Parages *et al.* 2016). More precisely, ENSO events typically generate a Tropical
Northern Atlantic pattern (TNA) and induce two separate atmospheric wavetrains (centered
12 respectively on the Pacific and Atlantic Oceans) (López-Parages *et al.* 2016, Rodríguez-Fonseca *et al.*
et al. 2016). Notably, in the case of ENSO events, the response to rainfall, sea level pressure and
14 wind is often more linear in the tropics but can be strongly non-linear in the extratropics (Frauen *et al.*
et al. 2014).

16 Recent works have applied atmospheric circulation models to explicitly simulate the
interactions between ENSO events and ocean multidecadal thermal state (Frauen *et al.* 2014,
18 López-Parages *et al.* 2016). These works have implemented numerical experiments in models
forced by idealized ENSO-AMO patterns (López-Parages *et al.* 2016). The resulting simulations
20 indicate that AMO and ENSO can jointly modulate the patterns of atmospheric Rossby wave
trains, and significantly alter extratropical drought responses (Supplementary Fig. 20). Under
22 negative AMO phases (i.e. during the 1970s), the model simulations and observational data
indicate enhanced Rossby wave train activity linked to a weakened jet in zones characterised by
24 negative meridional thermal gradients (López-Parages *et al.* 2015, Rodríguez-Fonseca *et al.* 2016).
Under negative AMO phases (i.e. during the 1970s), the model simulations and the observational

data indicate enhanced Rossby wave train activity triggered by ENSO over the North Atlantic
sector. This fact is related to a weakened jet in zones characterised by negative thermal gradients
(López-Parages *et al.* 2015, Rodríguez-Fonseca *et al.* 2016). Thus, under cold North Atlantic SST
conditions, the models indicate an enhanced wave activity triggered by ENSO and connecting the
Pacific basin and the Atlantic European region (Supplementary Fig. 20). In these conditions, the
ENSO-related wave activity flux (m^2/s^2) crossing the North Atlantic at upper troposphere (200
hPa) triggers in turn a deep low-pressure system over the British Islands, producing significantly
increased rains in Northern Europe and significantly increased drought conditions in semi-arid
Mediterranean areas (López-Parages *et al.* 2015, 2016). Overall, the available modelling evidence
and the observational results (Figs. 4 and 5, Supplementary Fig. 20) suggest an important role for
modified Rossby wave trains associated with multidecadal ENSO-AMO variability, potentially
effecting drought and forest carbon regime shifts.

The results indicate that AMO has a large influence on long-term multidecadal drought and carbon
uptake dynamics. AMO is significantly associated with increased spring and summer drought
conditions at the multidecadal scale, affecting land temperatures, water vapour transport over land
and standardised drought indicators (SPEI) (Supplementary Fig. 17). The observed effects of
AMO on the climatic variables are mainly concentrated in the March-October period
(Supplementary Figs. 17-18). These results add to previous studies documenting a pervasive
influence of AMO on several components of the climatic system (reviewed in Supplementary Box
1a). Beyond the effects of AMO and SSTs on atmospheric Rossby wave train dynamics, diabatic
processes linked to increased SSTs have multifaceted effects and influence multiple atmospheric
phenomena. These effects are reviewed in Supplementary Box 1b and include the alteration of the
Hadley and Walker cell size, shape and dynamics, the location and seasonal migration of the
intertropical convergence zone (ICTZ) and the tropical monsoon activity and its links to mid-

latitude zones. The reviewed evidence supports that these co-acting processes may also strongly
2 impact drought regimes.

A remaining question is how these mechanisms might be currently affected by ongoing
4 global warming and how they might evolve in the near future (see Supplementary Box 1c for a
detailed discussion). The AMO is linked to the Atlantic multidecadal overturning thermohaline
6 circulation (AMOC), which in turn currently stands as a major modulator of the responses of the
earth system to global warming (Chen & Tung 2014, Hansen *et al.* 2016, Sgubin *et al.* 2017,
8 Caesar *et al.* 2018, Thornalley *et al.* 2018). Moreover, global warming may strongly interact with
AMO in present day conditions and in future scenarios. For example, amplified ocean
10 multidecadal oscillations have been reported in the last decades and related to global warming
(Moore *et al.* 2017). These amplified oscillations suggest a scenario in which global warming
12 progressively increases the amplitude of AMO cycles in the next decades (Supplementary Fig.
21a). In line with these trends, less frequent and longer-lived oscillations have also been reported
14 for the Pacific Decadal Oscillation (PDO), producing a deepening of the ocean mixed layer
(Boulton & Lenton 2015).

In addition, global warming could also be promoting a progressive slowdown of the AMOC
16 (Supplementary Fig. 21b). In fact, an unprecedented reduced AMOC state has been recently also
18 discussed, presumably linked to global warming and increased Greenland ice sheet loss (Bamber
et al. 2012, Robson *et al.* 2014, Rahmstorf *et al.* 2015, Sgubin *et al.* 2017, Caesar *et al.* 2018,
20 Thornalley *et al.* 2018). Besides, AMO and ENSO influence wildfire occurrence (Kitzberger *et al.*
2015). Therefore, amplified AMO, changes in ENSO dynamics and global warming could jointly
22 affect fire frequency in the next decades and impact forest carbon sinks (Supplementary Fig. 21c).
In addition, Arctic climate amplification processes significantly interact with ocean multidecadal
24 phases. For example, recent works indicate that Arctic warming has been enhanced by the current
phase (PDO-, AMO+), leading to a reduction of the poleward temperature gradient and to reduced

westerlies (Screen & Francis 2016, Tokinaga *et al.* 2017, Su *et al.* 2017). Additional modelling
evidence has forecasted strong interactions between AMOC, AMO and global warming in the next
decades (Hansen *et al.* 2016, Sgubin *et al.* 2017).

Global warming is also expected to impact Rossby wave trains (Supplementary Fig. 21d). A
significant impact of Arctic amplification processes on atmospheric Rossby wave trains is
expected (Francis & Vavrus 2012, Coumou *et al.* 2015). Rising near-surface air temperatures in
the Arctic exceed mid latitude warming by a factor of at least two since the late 1990s (Francis *et al.*
2017). The amplification of Arctic temperatures by global warming typically promotes a
reduced poleward temperature gradient and slower eastward progression of Rossby waves (i.e.
weakened zonal winds and increased wave amplitude). Slower progression of waves in turn
produces more persistent associated weather patterns in mid-latitudes, increasing the probability of
extreme weather events (drought, flooding, cold spells, heat waves). ENSO dynamics might be
also altered by global warming, possibly increasing the frequency and intensity of Eastward
propagating ENSO events (Cai *et al.* 2015) (Supplementary Fig. 21e). Other works indicate that
global warming may also promote more persistent La Niña conditions (Mann *et al.* 2009,
McPhaden *et al.* 2015) (Supplementary Fig. 21f). For example, palaeoclimatic evidence from the
Medieval Climate Anomaly suggests that increased radiative forcing can increase La Niña-like
states (Mann *et al.* 2009, Marsicek *et al.* 2018). Global warming will also elevate tropical SSTs,
which in turn will possibly induce a more elevated outflow of the rising branch of the Hadley cell,
enhancing drought in semi-arid biomes at mid latitudes (Fu 2015, Lau & Kim 2015)
(Supplementary Fig. 21g). Under warmer SSTs, the rising air reaches a more elevated
tropopause, becoming dehydrated by colder temperatures, and drier air is produced when
subsiding at mid-latitudes in semi-arid regions (Fu 2015, Lau & Kim 2015). Finally, global
warming could progressively modify ocean-land interactions that intervene in the generation of
drought periods and the advection of ocean humidity over land (Fu 2015, McPhaden 2015)

(Supplementary Fig. 21h; Supplementary Box 2). In the context of increasing global warming, water vapor content over land may not increase fast enough relative to the rapid temperature warming, resulting in drier air masses in extensive continental areas of the globe (Sherwood & Fu 2014, Fu 2015). The relative balance between Arctic and Antarctic amplification could also alter globally ocean heat transport by AMOC, SST patterns, and impact global drought patterns (Supplementary Fig. 21i).

Overall, there is robust evidence suggesting notable impacts of global warming on the major components analysed, including AMO, ENSO and atmospheric Rossby wave trains. Grey circles in Supplementary Fig. 21 synthesize the expected major impacts of global warming that could in turn affect regime shifts in drought and forest carbon uptake. The future dynamics of atmospheric Rossby wave trains and the associated drought regimes at mid-latitudes will depend on the relative strength of different global warming amplification processes at different latitudinal bands (Supplementary Fig. 21a-i). For example, the co-occurrence of arctic positive feedbacks and tropical Hadley cell amplification processes is expected. The relative strength of tropical, arctic and antarctic amplification processes, though, will ultimately shape the meridional temperature gradient at mid-latitudes, determining in this way long-term Rossby wave train dynamics, the frequency of blocking activity and drought regimes in semi-arid areas (Francis *et al.* 2017). Due to the strong links and interactions reported for all the components reviewed, a wide range of possible scenarios should be considered.

Our results are consistent with previous studies of the responses of Aleppo pine to increased drought, which have extensively documented a reduction in growth and wood production as water availability decreases (Borghetti *et al.* 1998; De Luis *et al.* 2007; Sarris *et al.*, 2007; Camarero *et al.*, 2010, Pasho *et al.* 2012, Gazol *et al.* 2017, Novak *et al.* 2016, Peña Gallardo *et al.* 2018) and with the effects of climatic oscillators on tree growth trends in this area (reviewed in Camarero *et al.* 2011; Pasho *et al.* 2011, St George 2014, Madrigal-González *et al.*

2017, Dorado-Liñán et al. 2017). Extending this previous evidence, our results highlight a critical importance of sustained, multidecadal negative effects of climatic teleconnections in forest carbon capture and resilience patterns (Fig. 2). We suggest that multiple and non-mutually exclusive mechanisms are jointly operating at different time scales shaping the reported trends on forest carbon capture, including the three analyzed climatic mechanisms (Fig. 6), but also lagged effects of soil hydrological and tree ecophysiological processes (Fig. 6). Referring to the ecophysiological processes, major negative effects of drought on the secondary growth of Aleppo pine have been mainly reported at a 8-12 month time scale after drought, but significant effects have been documented for longer time periods (lasting to 24-30 months; Pasho *et al.* 2011, Peña Gallardo *et al.* 2018). Experimental, xylogenesis and isotope studies indicate that wood formation and secondary growth are significantly constrained by early summer water availability and associated with drought-induced shifts in the stomatic control of leaf conductance (Borghetti *et al.* 1998, Ferrio *et al.* 2003, Gazol *et al.* 2017, Novak *et al.* 2016). Similarly, it is well documented in this species that climatic conditions during the growing season affect tree growth during the subsequent year (Sarris *et al.* 2007, Linares *et al.* 2010, Pasho *et al.* 2011). In line with these findings, Anderegg *et al.* (2015) also documented in a global comparative analysis of multiple forest types an incomplete forest growth recovery for 1 to 4 years after extreme drought, showing most prevalent negative effects in Pinaceae species, located in dry ecosystems, and in species with reduced hydraulic safety margins. On top of this, additional observational studies suggest that complex feedbacks between drought-induced defoliation, tree primary and secondary growth and carbon starvation might extend and lengthen tree recovery periods, limiting tree long-term resilience, and resulting in declining trends (e.g. Girard *et al.* 2009, Guada *et al.* 2016). Independently from these ecophysiological processes, intrinsically delayed responses of soil hydrological systems, affecting groundwater levels several months after the meteorological drought can also additionally contribute to the emergence of long-term tree responses (St George

2 *et al.* 2014). The limited early warning signals, low recovery rates and resilience trends reported
3 for Aleppo pine (Figs. 2, 3) are consistent with previous studies (Camarero *et al.* 2015a, Gazol *et*
4 *al.* 2018). Overall, despite the well-known importance of the reviewed ecophysiological processes
5 shaping long-term responses of secondary growth, our analyses suggest a major contributing role
6 of the reported climatic mechanisms on the reported regime shift (Fig. 4-6).

7 Previous studies of the dynamics of forest carbon uptake in the Iberian peninsula have
8 mainly focused on the 1986-2008 time period, i.e. the decades covered by the Spanish Forest
9 National Inventories. These studies have reported dominant effects on tree secondary growth of
10 stand structure, plantation effects, tree height, and functional diversity (reviewed in Gómez-
11 Aparicio *et al.* 2011, Vayreda *et al.* 2012, Coll *et al.* 2013, Ruiz-Benito *et al.* 2014), and
12 significant but quantitatively less dominant effects of climatic variables (Vayreda *et al.* 2012, Coll
13 *et al.* 2013). Our results identify a new ecological context dominated by strong, climate-induced
14 multidecadal shifts in forest productivity, with important reductions in annual productivity at the
15 decadal scale (31-37%) and significantly reduced resilience in Aleppo pine stands (Fig 2).

16 To conclude, in this study we have identified the key role of the non-stationary interactions
17 between AMO and ENSO events in driving abrupt climatic shifts in semi-arid Aleppo pine forests,
18 providing a new, unreported mechanism for carbon uptake shifts in these vulnerable forests. We
19 have provided as well evidence for other co-acting processes implied in the emergence of regime
20 shifts in drought and forest carbon uptake, and outlined a framework integrating the expected
21 effects of global warming in these mechanisms.

FIGURE 1. Drought-regime shifts. Observed shifts in monthly series of the Standard Precipitation Evapotranspiration Index (SPEI, 12-month window) at a grid resolution of 280×280 km² in the Spanish Iberian Peninsula. The year of a shift and the variance explained by the regression tree model are indicated. The splitting points obtained by the regression tree analyses for 1950-2012 are indicated by coloured vertical bars. Red bars indicate shifts characterized by $R^2 > 0.20$ and a Tukey-Kramer test p value < 0.0001 . Orange bars indicate significant shifts with regression tree $0.10 < R^2 < 0.20$ and a T-K test p value < 0.0001 . Yellow bars indicate $0.01 < R^2 < 0.10$ and a T-K test p value < 0.0001 . Green bars indicate a splitting point departing from the studied 1979 - 1981 period. Positive and Negative SPEI values indicate wet and dry periods, respectively. (a-m) Monthly SPEI series are shown for each grid unit.

FIGURE 2. Changes in carbon uptake by Mediterranean forests. (a) Carbon-uptake dynamics in 18 Aleppo pine forests situated in the northeastern Iberian Peninsula showing regime shifts in carbon uptake. Blue dots and lines represent the observed trends in carbon gain during the first three decades. Red dots and lines illustrate the observed dynamics after the 1980s climate shift. Significant linear trends are shown (ordinary least squares regression). Smoothed trends fitted by the cubic spline method are represented (λ values = 0.01 and 100). (b) Observed trends in forest carbon uptake synchrony. A spline fit (black line) indicates the averaged r pearson trend observed for all forest stands ($\lambda=100$). The contour lines are quantile contours in 5% intervals (i.e. 5% of the r pearson values are below the lowest (blue) contour, 10% are below the next contour, red contour lines indicate maximum point density). (c) Observed trends in the forest carbon uptake resilience index after the 1980 regime shift. A spline fit (black line) indicates the mean FCUR trend observed

18

20

22

24

26

for all forest stands ($\lambda=100$). FCUR is calculated using a reference period of 5 years before the shift. A smooth coloured surface illustrating the density distribution of FCUR values is provided. Red contour lines indicate maximum FCUR point density. The contour lines are quantile contours in 5% intervals. (d) Observed trends in forest carbon uptake recovery capacity (FCURC). The thin dashed black line indicates the minimum FCU level observed the year of the regime shift. A spline fit (black line) indicates the averaged FCURC trend observed for all forest stands ($\lambda=100$). Red contour lines indicate maximum FCURC point density.

FIGURE 3. Analyses of early-warning signals and structural equation models (SEM). (a) A comparison of the early-warning signals (AR-1) observed for SPEI variables and forest carbon uptake ($\text{kg ha}^{-1} \text{y}^{-1}$). (b) Observed relationship between SPEI early-warning signals (AR-1) and regime shift strength (variance explained by regression tree models). (c) Relationship between the nonparametric Kendall tau correlation coefficient for the AR-1 moment (based on the SPEI 12-month time series during the 1950-1979 period) and the variance explained by the regression tree models ($1/\text{AICc}$). (d) Standardised coefficients in the SEM model for grid cell g ($280 \times 280 \text{ km}^2$ scale, Supplementary Fig. 1). Model-fitting parameters: $\chi^2=3.04$, $p=0.36$; $\text{BIC}=-16.81$. (e) Relationship between the standardised coefficients in the SEM models linking AMO and SPEI and the variation explained by the regression tree analyses ($1/\text{AICc}$). (f) Relationship between the nonparametric Kendall tau correlation coefficient and the standardised coefficients of the SEM connecting AMO and SPEI 12.

FIGURE 4. Changes in the non-stationary effects of the El Niño Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO) on the SPEI drought index. (a) Upper panel. Observed changes in the Atlantic Multidecadal oscillation (AMO) and the Multivariate

ENSO Index (MEI) over 1950-2012, reporting a parallel shift in the vicinity of 1980. Low-
2 frequency variability in the annual AMO and MEI index are illustrated (Spline fits,
Lambda_{AMO}=10, Lambda_{MEI}=100). Lower panel: Observed variation in the number of months per
4 year with significant effects ($p<0.05$) of the Multivariate ENSO index (MEI) on seasonal drought
(SPEI, three month temporal scale). Red squares indicate significant negative effects associated
6 with increased drought (increased number of months with significant drought effects). Blue
squares indicate positive effects associated with increased autumn rains ($p<0.05$). (b) Observed
8 low frequency changes in the monthly winter NAO index over 1950-2012. Trends for January are
illustrated (Spline fit). The same trends were observed for December (not shown). Thick blue line:
10 Lambda=10000. Thin blue line: Lambda=1000. Lower panel: Observed variation in the effects of
winter NAO on drought (SPEI 3). Significant negative effects of NAO on SPEI ($p<0.05$) were
12 detected on December and January. Red squares illustrate the detection of significant negative
effects of monthly winter NAO states (December and January) on SPEI ($p<0.05$).

14

16 **FIGURE 5. Modulation induced by the Atlantic ocean multidecadal variability (AMO) on**
the correlations between ENSO and forest carbon uptake (FCU). (a) Observed negative
18 correlations between Pearson correlation values (rFCU-MEI) and AMO in the 18 Aleppo pine
stands experiencing regime shift trends. Correlations were computed for all months, and the
20 maximum correlation value observed is illustrated. * $p<0.05$, ** $p<0.01$. (b) A summary of the
observed variation of the strength of the modulation by AMO (explained variance) and its monthly
22 variation. The plot synthesises the observed relationships at 18 forest sites and for all the months
of the year. A quadratic polynomial fit is shown. (c) Observed p values for the reported

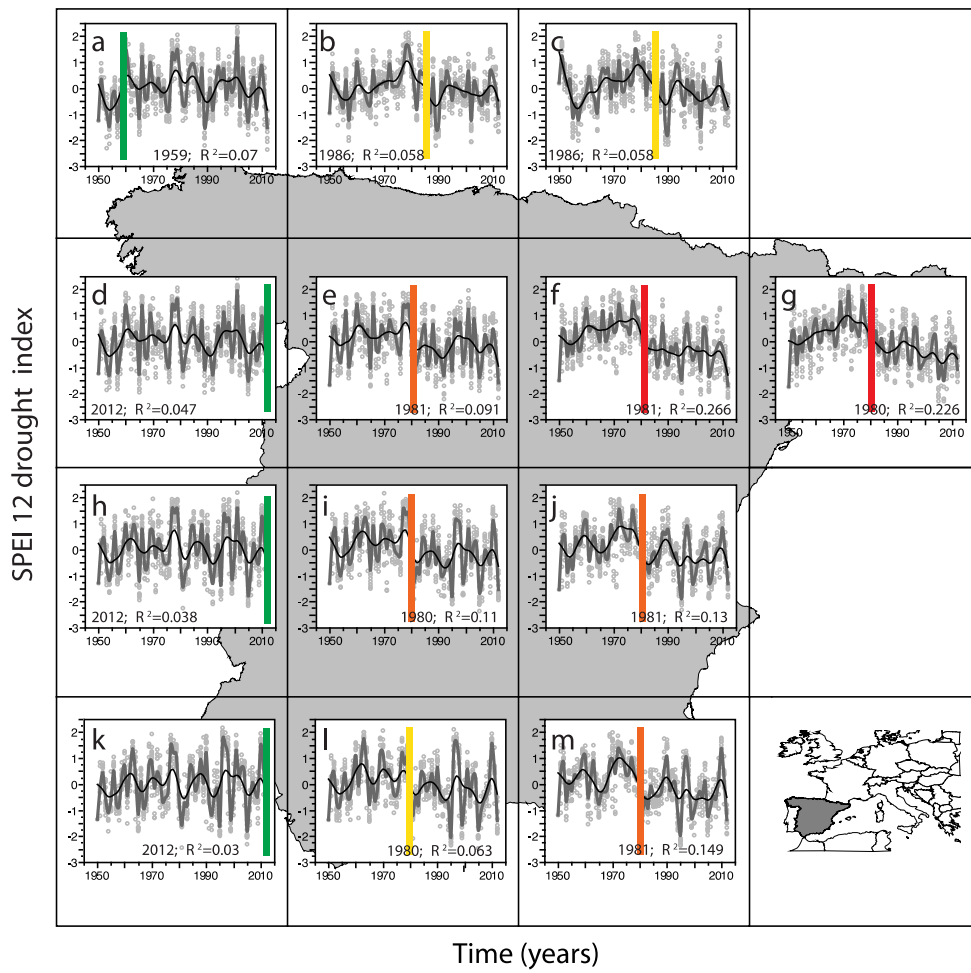

2 correlations in b. In b and c a smooth surface showing the density of data points is provided. Red
contour colors indicate maximum point density.

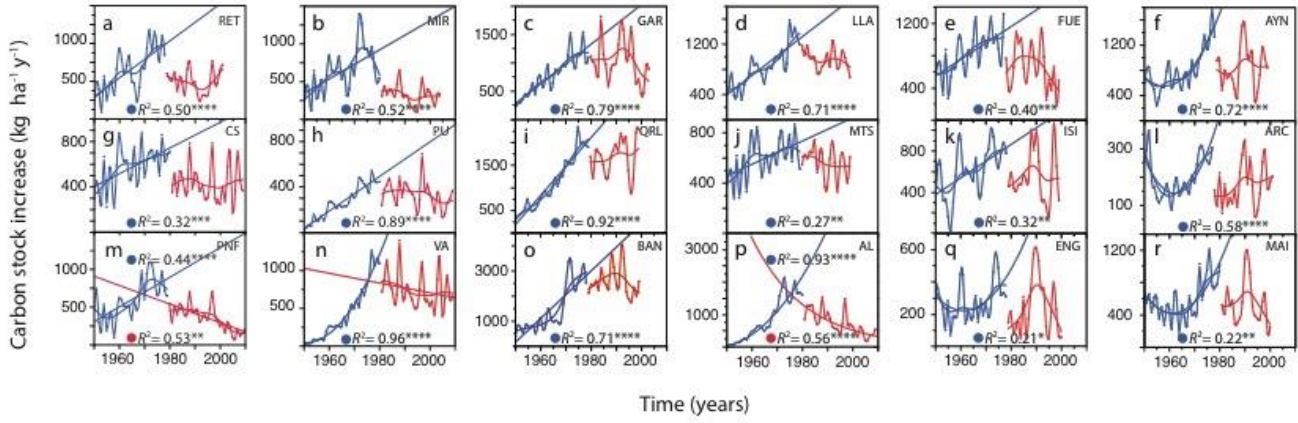

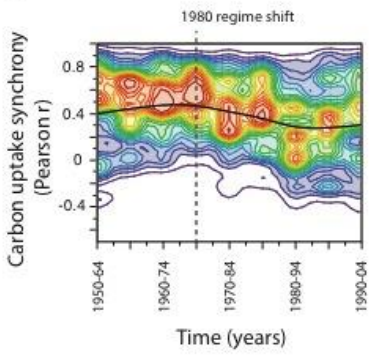

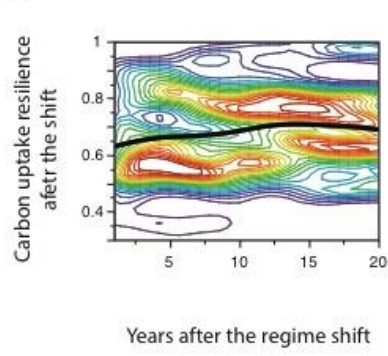

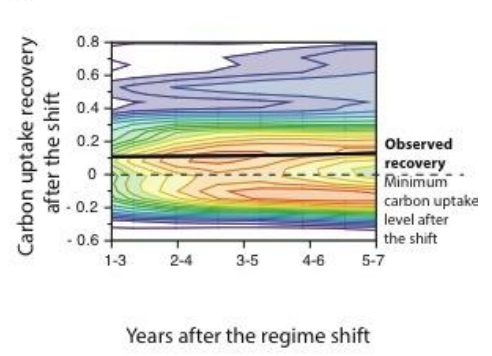

4 **FIGURE 6. A diagram illustrating three mechanisms affecting drought trends and regime**
5 **shifts in forest carbon uptake.** Sea surface temperatures (SST) depend on positive/negative
6 AMO phases and ENSO, and modulate the propagation of Rossby waves and the transport of
7 water vapour and heat over land. AMO also has lagged effects on the dynamics of winter NAO,
8 which in turn significantly affect drought severity and atmospheric blocking frequency leading to
9 reduced forest carbon uptake.
