### ABSTRACT

The regimen of carfilzomib, daratumumab, and dexamethasone (KdD) shows activity in patients with relapsed/refractory multiple myeloma. KdD at the twice-weekly 56 mg/m<sup>2</sup> carfilzomib dose (KdD56) was used in the randomized phase 3 CANDOR study (NCT03158688), whereas KdD at the once-weekly 70 mg/m<sup>2</sup> carfilzomib dose (KdD70) was used in the phase 1 b EQUULEUS study (NCT01998971). We analyzed efficacy data from comparable CANDOR and EQUULEUS patients using inverse probability of treatment weighting (IPTW)-adjusted models. These weights were calculated from propensity scores derived to balance prespecified baseline covariates. The side-by-side and adjusted comparisons showed similar efficacy for overall response rates and progression-free survival in the two groups, with a series of sensitivity analyses showing consistent findings. Safety data were generally consistent with the known safety profiles of each individual drug. Once-weekly KdD70 is comparable to twice-weekly KdD56 in terms of efficacy and safety while being a more convenient dosing option.

## Introduction

Regimens containing immunomodulatory imide drugs (IMiDs) are standard of care for the treatment of newly diagnosed multiple myeloma [1–5]. With the adoption of lenalidomide maintenance therapy until disease progression, there is a further need for effective and tolerable IMiD-free regimens for patients who progress on lenalidomide. Worse clinical outcomes are seen in patients with relapse with IMiD refractoriness when compared with the overall population [6–9], with relapse due to various mechanisms of drug resistance

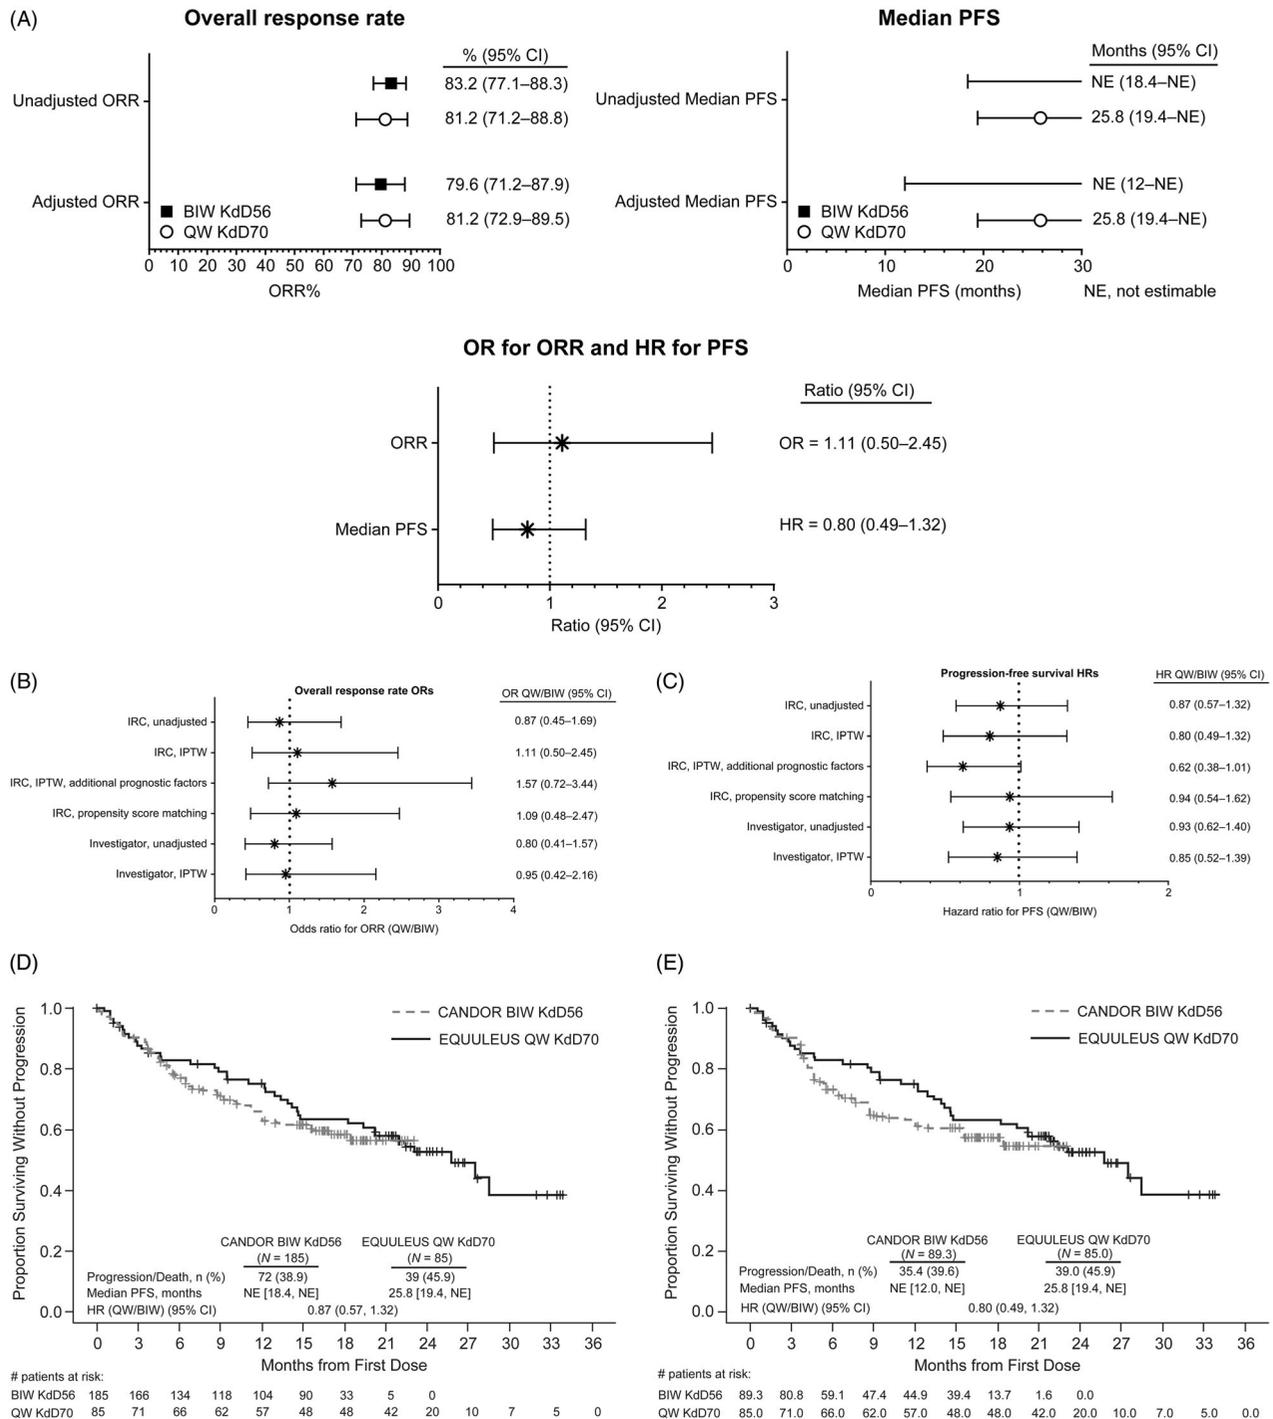

and alterations in the bone marrow microenvironment [10]. The second-generation proteasome inhibitor (PI) carfilzomib and the anti-CD38 monoclonal antibody daratumumab are potent agents in their respective classes [11–15]. In the phase 3 ENDEAVOR study, carfilzomib plus dexamethasone (Kd) showed superiority over the first-generation PI bortezomib plus dexamethasone (Vd) in relapsed and/or refractory multiple myeloma [11,16]. Likewise, the phase 3 CASTOR study demonstrated improved clinical outcomes for daratumumab with bortezomib and dexamethasone

compared with bortezomib and dexamethasone alone [17]. The regimen including carfilzomib and daratumumab is of high interest to clinicians for relapsed and/or refractory multiple myeloma.

The randomized phase 3 CANDOR study demonstrated a statistically significant improvement in progression-free survival (PFS) for carfilzomib, dexamethasone, and daratumumab at the twice-weekly 56 mg/m<sup>2</sup>

carfilzomib dose (KdD56), with a 37% reduction in the risk of progression or death versus carfilzomib and dexamethasone alone (Kd) [18]. Additionally, patients treated with KdD56 achieved deep responses, with an overall response rate (ORR) of 84% and a nearly 10 times higher minimal residual disease (MRD)–negative complete response (CR) rate compared with Kd-treated patients. Overall, KdD56 was associated with a favorable benefit-risk profile. The promising activity of the KdD regimen is further supported by the non-randomized phase 1b EQUULEUS study, in which KdD at the once-weekly 70 mg/m<sup>2</sup> carfilzomib dose (KdD70) showed tolerability and efficacy, with an ORR of 84% and median PFS of nearly 26 months in patients who were almost all exposed to lenalidomide and were mostly lenalidomide refractory [19].

Previously, the phase 3 A.R.R.O.W. study demonstrated that once-weekly Kd (Kd70) was effective and safe [20]; this regimen achieved regulatory approval for the treatment of relapsed and/or refractory multiple myeloma in the United States and elsewhere.

Patient-reported outcomes from the A.R.R.O.W. study showed delayed disease symptom worsening as well as greater convenience and satisfaction with once-weekly Kd70 as compared with twice-weekly Kd27. Improved clinical outcomes for the once-weekly Kd regimen translated into prolonged health-related quality of life in a cost-effective manner [21,22]. Thus, as observed with the Kd regimen, once-weekly carfilzomib dosing with KdD is expected to improve patients' quality of life by allowing patients to maintain a social role and other meaningful activities, which is key from a patient's perspective [23].

While we expect that the once-weekly KdD70 regimen would provide patients a more convenient treatment option and thus better adherence, the two regimens of twice-weekly KdD56 and once-weekly KdD70 have not been directly compared in a randomized trial. Therefore, we performed a robust cross-study comparison that demonstrated similar efficacy and safety, which was confirmed with sensitivity analyses.

## Methods

### Study design

CANDOR is a phase 3, open-label, multicenter, randomized study in patients with relapsed and/or refractory multiple myeloma who received 1–3 prior lines of therapy (NCT03158688). Patients were randomized 2:1 to receive KdD or Kd in 28-day cycles until disease progression (Figure S1A, Table S1). Treatment continued until confirmed disease progression, unacceptable toxicity, consent withdrawal, or death (whichever occurred first), and lasted up to 48 months. The primary endpoint was PFS; secondary endpoints were ORR, MRD-negative CR rate at 12 months, overall survival (OS), time to response, and safety. Data are through July 14, 2019 (primary analysis date).

EQUULEUS is a phase 1b, multicenter, open-label, multiarm, non-randomized study of daratumumab in combination with other agents in patients with relapsed and/or refractory multiple myeloma (NCT01998971) (Figure S1B, Table S1). One cohort combined daratumumab with carfilzomib and dexamethasone (i.e. KdD), which is the dataset described here and elsewhere [19]. Patients received 1–3 prior lines of therapy, including bortezomib and an IMiD. Treatment continued until confirmed disease progression, unacceptable toxicity, withdrawal of consent, death, or end of study, which was approximately 25 months after the last patient received the first dose of daratumumab or when 38 PFS events were reached. The primary endpoints were safety and tolerability. Secondary endpoints included ORR and OS; PFS was an exploratory endpoint. Data are through January 31, 2019 (final analysis date for this cohort). In the original report, the number of patients evaluable for response per study criteria was 82 of 85; all 85 patients are included in our analyses.

### Statistical analysis

This cross-study comparison was a prespecified meta-analysis exploring the similarity between the efficacy and safety outcomes for patients treated with the triplet combination KdD in two different studies. The efficacy data were analyzed both unadjusted and with propensity score adjustment, while safety data were summarized in side-by-side tables.

In order to evaluate efficacy in comparable populations, as all patients from the EQUULEUS KdD cohort were required to have prior therapy with bortezomib and an IMiD, similar patients (i.e. those with prior bortezomib and IMiD exposure) were selected from the

CANDOR KdD arm; 185 of the 312 patients in the CANDOR study receiving KdD met this requirement. All these patients had at least one study treatment dose and were included in the safety summaries. The efficacy endpoints were derived based on the response and disease progression from both studies assessed post hoc by the same blinded Independent Review Committee (IRC). The PFS endpoint was analyzed using Cox models, while the Kaplan-Meier methodology was used to summarize its distribution, including the point estimates and 95% confidence intervals (CIs) for medians [24]. ORRs were calculated as the rate of responders who achieved a partial response (PR) or better and associated 95% CIs were estimated with the Clopper-Pearson method. Odds ratios (ORs) were evaluated with logistic models, while 95% CIs were constructed with robust variance estimates.

For efficacy comparisons, results were adjusted with inverse probability of treatment weighting (IPTW). The weights were calculated using the propensity score that a patient received once-weekly KdD70 by balancing the baseline covariates that had been preselected as prognostic for multiple myeloma. Selection of these covariates was independent of prior knowledge of efficacy outcomes and was based on subject matter expert guidance and literature review. The covariates included baseline demographics (age), disease characteristics (prior treatment exposure/refractoriness and time from initial diagnosis to relapse), and other characteristics (creatinine clearance, Eastern Cooperative Oncology Group [ECOG] performance status), many of which have been evaluated in previous carfilzomib analyses [25]. We did not include all components of the revised International Staging System (R-ISS) as data were not available for all patients for fluorescence *in situ* hybridization (FISH) and as  $\beta$ 2 microglobulin data were not collected in the EQUULEUS study.

The appropriateness of the model was assessed by boxplots and absolute standardized difference, evaluating the balance reached between the two groups after weighting adjustment. Propensity score matching was also used as a sensitivity analysis by sequentially matching patients based on greedy nearest neighbor matching of the propensity scores derived for the IPTW method. Propensity score matching creates mutually exclusive sets of observations that have similar propensity scores. Greedy nearest neighbor matching was used to sequentially match each patient in the KdD70 cohort with one patient in the KdD56 external control group if the difference in the logits of the propensity score for pairs of patients from the two

BIW: twice weekly; ECOG: Eastern Cooperative Oncology Group; IMiD: immunomodulatory imide drug; KdD: carfilzomib, dexamethasone, and daratumumab; QW: once weekly; SD: standard deviation. Absolute standard difference was a prespecified method used to quantify the balance for each covariate; an absolute standard difference of ≤0.1 signifies little or no imbalance between KdD BIW and KdD QW for that variable.

<sup>a</sup>The N = 89.3 is not a whole number as it represents a weighted sum of the 185 KdD56 CANDOR patients included in the analysis. Specifically, each patient of the KdD56 arm was weighted according to the inverse probability of treatment weighting (IPTW) based on the propensity score to have received KdD70, balancing for the baseline covariates included in this table. As these weights were not whole numbers, the sum of these weights was also not necessarily a whole number (in this case, the sum was 89.3).

groups was less than or equal to 0.1 times the pooled estimate of the standard deviation [26,27]. Efficacy endpoints derived based on unblinded evaluations by the investigators were included as a sensitivity analysis. In addition, PFS and ORR were analyzed within prespecified subgroups, including by the number of prior regimens, prior transplant, refractoriness to PIs or IMiDs, age, ECOG performance status, and baseline creatinine clearance. The hazard ratios (HRs; with 95% CIs) for PFS and ORs (with 95% CIs) for ORR between treatment groups within each subgroup were estimated using the same methodology as for the overall analysis.

## Results

### Demographic and baseline characteristics

Baseline demographic and disease characteristics were generally comparable between the two groups in this analysis: twice-weekly KdD56 CANDOR arm (i.e. CANDOR subset with prior bortezomib and IMiD exposure) and once-weekly KdD70 EQUULEUS cohort. However, some baseline characteristics were imbalanced across the studies (Table 1). Specifically, in the KdD70 cohort, more patients had a higher ECOG performance status, at least two prior treatments, and prior exposure to lenalidomide, and disease duration was longer than in the KdD56 arm. Following IPTW adjustment, baseline and disease characteristics

considered prognostic were balanced for the two groups (Table 2).

At the time of this analysis, 48% of CANDOR patients and 41% of EQUULEUS patients were continuing treatment. Of patients who discontinued treatment, the most common reasons for discontinuation were disease progression (CANDOR: 27%, EQUULEUS: 42%), adverse events (AEs, 10%, 6%), and per patient request (7%, 7%) (Table S2).

### Efficacy

In a side-by-side comparison, after a median follow-up of 16.8 months, median PFS for the KdD56 group was not reached (not estimable [NE]; 95% CI, 18.4–NE), whereas for the KdD70 cohort, median PFS was 25.8 months (95% CI, 19.4–NE, median follow-up of 23.5 months) (Table 3, Figure 1(A)). PFS event-free rates at 12 months were 64.9% (95% CI: 57.3%–71.4%) for KdD56 and 75.2% (95% CI: 64.2%–83.2%) for KdD70 (graph in Figure 1(D,E)). ORR was 83.2% (95% CI, 77.1%–88.3%) for KdD56 and 81.2% (95% CI, 71.2%–88.8%) for KdD70. After IPTW adjustment, the 95% CI for the HR for PFS and the OR for ORR included 1, showing similar efficacy for the KdD56 and KdD70 groups (median PFS, NE and 25.8 months, respectively [HR, 0.80; 95% CI, 0.49–1.32]; ORR, 79.6% and 81.2%, respectively [OR, 1.11; 95% CI, 0.50–2.45]).

<sup>a</sup>The  $N = 89.3$  is not a whole number as it represents a weighted sum of the 185 KdD56 CANDOR patients included in the analysis. Specifically, each patient of the KdD56 arm was weighted according to the inverse probability of treatment weighting (IPTW) based on the propensity score to have received KdD70, balancing for the baseline covariates included in this table. As these weights were not whole numbers, the sum of these weights was also not necessarily a whole number (in this case, the sum was 89.3).

Additional sensitivity analyses were performed to support the robustness of the main comparison results. One sensitivity analysis for efficacy results adjusted for IPTW using an extended list of covariates, specifically laboratory values for albumin, hemoglobin, lactate dehydrogenase (LDH), and platelet count, and the presence of plasmacytoma, in addition to the covariates included in the main analysis, yielded consistent results. Efficacy results adjusted by propensity score matching showed similar results as well. In another sensitivity analysis, the adjusted and unadjusted comparisons performed on investigator-assessed ORR and PFS yielded similar findings to those performed on IRC-assessed ORR and PFS (Figure 1(B,C), Tables SIII, SIV). Prespecified subgroup analyses (e.g. number of prior regimens, prior transplant, refractoriness to PIs or IMiDs, age, ECOG performance status, baseline creatinine levels) were consistent with the results from the main analysis for PFS and ORR outcomes, including in the lenalidomide-refractory subgroup and by prior transplant status (Table 4).

### Exposure and safety

The median duration of carfilzomib treatment was shorter for the twice-weekly KdD56 group (54.3 weeks) than for the once-weekly KdD70 cohort (66.0 weeks) and the median relative dose intensity was similar for both groups at approximately 90%. Safety analyses were performed side-by-side for all patients with no adjustment. All-grade treatment-emergent adverse events (TEAEs) occurred in 100% of patients in both groups (Table 5). Over the course of the studies (i.e.

not duration-adjusted), the unadjusted frequency of grade  $\geq 3$  TEAEs was similar in the KdD56 and KdD70 groups (84.3% and 82.4%, respectively), while the incidence of serious (58.9% and 48.2%) and fatal (10.8% and 3.5%) TEAEs was higher in the KdD56 group. For fatal AEs, of the 20 in the KdD56 group, 10 were due to infections (five septic shock, four pneumonia, one respiratory tract infection), whereas for the three fatal AEs in the KdD70 cohort, two were due to general physical health and one due to multiple organ dysfunction. The proportions of patients with AEs leading to carfilzomib discontinuation (21.1% for KdD56 and 18.8% for KdD70) and daratumumab discontinuation (8.1% and 8.2%) were comparable between the two treatment groups. For AEs of interest, the rates of grade  $\geq 3$  AEs in the KdD56 and KdD70 groups, respectively, were 1.1% and 2.4% for cardiac failure, 0.5% and 3.5% for acute renal failure, 18.4% and 20.0% for hypertension, and 2.7% and 0.0% for respiratory tract infections. For the category of grade  $\geq 3$  infections/infestations, the rate was higher with KdD56 than with KdD70 (36.8% and 21.2%, respectively). These same general trends were seen in exposure-adjusted rates of AEs; however, conclusions are limited as there were relatively few events for several AEs of interest in both studies.

### Discussion

The KdD regimen is recommended by the National Comprehensive Cancer Network (NCCN 2020, version 3) guidelines for patients with previously treated multiple myeloma [4]. As weekly carfilzomib dosing can be more convenient and improve the quality of life [21,22], we undertook rigorous efficacy analyses in this cross-study comparison to support the comparability of twice-weekly KdD56 to once-weekly KdD70. We found that the corresponding groups of the CANDOR and EQUULEUS studies showed similar efficacy in terms of ORR and PFS, both before and after IPTW adjustment, including in patients who were refractory to lenalidomide and independent of past stem cell transplant status. We also examined safety in side-by-side unadjusted analyses and found that the safety profiles of KdD56 and KdD70 were generally consistent with the known safety profiles of the individual agents. The proportions of patients with grade  $\geq 3$  AEs were similar in the KdD56 and KdD70 groups and the incidences of grade  $\geq 3$  cardiac AEs, renal failure, hypertension, and respiratory tract infections did not differ appreciably. However, there were more grade  $\geq 3$  infectious AEs and fatal infections with KdD56

**Table 4.** Efficacy results for selected subgroups.

BIW: twice weekly; CI: confidence interval; D/C: discontinuation of; KdD: carfilzomib, dexamethasone, and daratumumab; NA: not applicable; QW: once weekly. NC indicates that exposure-adjusted adverse event rates were not calculated as collection of adverse events can vary across studies, making interpretation of rates of all adverse events across studies infeasible. Safety data were compared side-by-side without any propensity score adjustment.

<sup>a</sup>By system organ class category; other adverse events are preferred terms.

than with KdD70. Although the benefit-risk profile was similar for both regimens, the once-weekly carfilzomib regimen may be more convenient for patients and healthcare providers. The more convenient regimen may improve adherence to the on-label carfilzomib dosing and frequency, and thus optimize carfilzomib dose intensity and outcomes in the real-world setting, as suboptimal carfilzomib dose intensity has been shown to be associated with poorer outcomes [28].

Direct comparisons across studies can be confounded by differences in study design, including eligibility criteria that result in patient populations with different characteristics, such as prior treatment history, leading to biased estimates of treatment effects [29–33]. To account for this, the propensity score

method was used to balance prespecified baseline covariates selected to be prognostic for multiple myeloma, with the goals of controlling for potential confounding factors of cross-trial comparison and minimizing selection bias. The IPTW/propensity score approach is a well-established method intended to mirror the effects of randomization [34,35]. Specifically, adjustment for selection bias was done by weighting the data based on the propensity score that a patient received once-weekly KdD70. As IPTW is based on covariates selected as prognostic for multiple myeloma outcomes, the methodology was applied to efficacy data, but not to safety events. Other studies evaluating treatment outcomes among patients with hematologic malignancies have also used propensity

score analysis to compare two distinct study populations and achieve balance in baseline factors [36,37]. Besides possible confounding due to the nature of cross-study comparisons, another limitation of this analysis was that baseline covariates in this analysis did not include R-ISS as  $\beta$ 2 microglobulin data were not collected in the EQUULEUS study and as FISH data were not available for many patients in both studies. However, LDH and albumin levels, two components of R-ISS, were used as additional variables, along with platelet count, hemoglobin, and plasmacytoma presence, in a sensitivity analysis. In this sensitivity analysis, there appears to be a larger effect size associated with KdD70 versus KdD56 for both ORR and PFS. This sensitivity analysis may have reduced residual confounding; however, the 95% CIs still included 1.

Previously, once-weekly carfilzomib dosing with Kd70 was shown to have improved patients' quality of life with improved clinical outcomes relative to twice-weekly carfilzomib dosing [21–23]. In line with these results for the once-weekly Kd70 doublet regimen, we expect that the once-weekly KdD70 triplet regimen will provide patients a more convenient lenalidomide-free treatment option, thus fostering adherence to the treatment schedule, dose, and treatment duration. Future analyses could confirm whether a weekly regimen is associated with better adherence and improved responses and survival. In addition, in the era of COVID-19, guidelines have recommended switching patients from twice-weekly to weekly carfilzomib at an appropriate dose [38,39], thus decreasing patients' potential exposure to coronavirus as well as enabling adherence and reducing strain on the healthcare system during a time when non-emergent visits to healthcare facilities should be limited. As the recently approved subcutaneous daratumumab [40] becomes more widely available, the treatment option of weekly KdD may result in further improvements in patient satisfaction, since use of subcutaneous daratumumab has been associated with higher patient satisfaction versus intravenous daratumumab [41], as would be expected with reduced infusion chair time and decreased infusion-related reactions.

In conclusion, this cross-study analysis showed that once-weekly KdD70 in the EQUULEUS study is comparable to the twice-weekly KdD56 regimen used in the pivotal phase 3 CANDOR trial in terms of efficacy and safety. The weekly KdD70 dosing option addresses an important need for patients by providing a more convenient lenalidomide-free regimen that may

encourage adherence and potentially lead to improved outcomes for patients.

## Acknowledgments

Amgen conducted the CANDOR study; Janssen conducted the EQUULEUS study. Amgen funded the analyses for this publication. Medical writing assistance was provided by Susanna Mac and Jacqueline Sayyah, both of Amgen.

## Author contributions

Monica Khurana, Mihaela Obreja, and Jianqi Zhang contributed to the conception and design of the analyses. All authors had a role in collection of data, analyzing and interpreting data, and reviewing the manuscript.
