The asymptotic relative efficiency and the ratio of sample sizes when testing two different null hypotheses

Guadalupe Gómez*,1 and Moisés Gómez-Mateu1

Abstract

Composite endpoints, consisting of the union of two or more outcomes, are often used as the primary endpoint in time-to-event randomized clinical trials. Previously, Gómez and Lagakos provided a method to guide the decision between using a composite endpoint instead of one of its components when testing the effect of a treatment in a randomized clinical trial. Consider the problem of testing the null hypotheses of no treatment effect by means of either the single component or the composite endpoint. In this paper we prove that the usual interpretation of the asymptotic relative efficiency as the reciprocal ratio of the sample sizes required for two test procedures, for the same null and alternative hypothesis, and attaining the same power at the same significance level, can be extended to the test procedures considered here for two different null and alternative hypotheses. A simulation to study the relationship between asymptotic relative efficiency and finite sample sizes is carried out.

Keywords: Asymptotic relative efficiency, composite endpoint, logrank test, sample size, simulation, survival analysis.

1. Introduction

In clinical trials research, one of the most important issues that investigators have to solve at the design stage of the study is the appropriate choice of the primary endpoint. Composite endpoints (CE) consisting of the union of two or more outcomes are commonly used as primary endpoints. For example, in the cardiovascular area the

relevant endpoint of death is often combined with other additional endpoints such as myocardial infarction, stroke or hospitalization. Pros and cons on the use of CE have been extensively discussed (Freemantle et al., 2003; Ferreira-González et al., 2007, among many others). One of the main advantages of using a CE relies in the fact that by means of a CE the problem of multiplicity is adequately addressed and the bias associated with competing risks (Wittkop et al., 2010) is avoided. Also, with a CE the number of observed events will be higher and, hopefully, the power of the test will increase. However, as it has been discussed (Montori et al., 2005) and shown in Gómez and Lagakos (2013), adding inappropriate components to the relevant endpoint might actually lead to a decrease in the power of the test statistic, consequently having a larger chance to fail in detecting a real effect of the treatment under study.

Gómez and Lagakos (2013) developed a methodology to help to decide when it is worthwhile to base the analysis on the composite endpoint \( E_{\text{e}} = E_1 \cup E_2 \) where \( E_1 \) and \( E_2 \) are two candidate relevant endpoints to evaluate the effect of a treatment instead of sticking to one of them, \( E_1 \), say. In order to do so, they compared how more efficient than \( E_1 \) would \( E_{\text{e}} \) be to justify its use. Let \( H_0 \) be the null hypothesis of no treatment effect evaluated on \( E_1 \) and denote by \( H_a \) an alternative hypothesis, for instance, claiming to delay the event \( E_1 \). Analogously, define \( H^*_0 \) and \( H^*_a \) the null and alternative hypotheses if the treatment effect is to be evaluated on \( E_{\text{e}} \). Since when comparing two treatment groups based on time-to-event endpoints, the primary analysis would be based, very commonly, on a logrank test, their method considers the logrank test \( Z \) to test \( H_0 \) versus \( H_a \) and the logrank test \( Z_e \) to test \( H^*_0 \) versus \( H^*_a \). The asymptotic relative efficiency (ARE) of \( Z_e \) versus \( Z \) is the measure proposed to choose between \( E_1 \) and \( E_{\text{e}} \), with values larger than 1 in favour of \( E_{\text{e}} \). This relative measure can be computed as \((\mu_*/\mu)^2\) where \( \mu \) and \( \mu_* \), are, respectively, the asymptotic means of \( Z \) and \( Z_e \), under alternative contiguous hypotheses to \( H_0 \) and \( H^*_0 \). The purpose of this paper is to prove that the usual interpretation of the ARE, as the ratio of sample sizes, \( n \) and \( n_* \), needed to attain the same power for a given significance level, still holds even though two different sets of hypothesis (\( H_0 \) versus \( H_a \) and \( H^*_0 \) versus \( H^*_a \)) are compared.

To clarify the purpose of our investigation consider the following. If we were to test \( H_0 \) versus \( H_a \) with two different test statistics \( S_n \) and \( T_m \), Pitman’s relative efficiency would be defined as the ratio \( m/n \), where \( n \) and \( m \) are the required sample sizes for \( S_n \) and \( T_m \), respectively, to attain the same power for a given significance level. Furthermore, if both \( S_n \) and \( T_m \) are asymptotically normal with unit variance and means \( \mu_S \) and \( \mu_T \), it can be proved that Pitman’s ARE corresponds to the square of the ratio of the noncentrality parameters, that is \((\mu_S/\mu_T)^2\). Gómez and Lagakos’ method compares the logrank statistics: \( Z \) and \( Z_e \) derived for two different set of hypotheses \( H_0 \) versus \( H_a \) and \( H^*_0 \) versus \( H^*_a \) and do so using, as definition of the ARE, the ratio \((\mu_*/\mu)^2\) where \( \mu \) and \( \mu_* \) are, respectively, the asymptotic means of \( Z \) and \( Z_e \), under alternative contiguous hypotheses to \( H_0 \) and \( H^*_0 \).

This paper is organized as follows. In Section 2 the notation, assumptions and main results from Gómez and Lagakos’ paper are introduced. Section 3 establishes
the limiting relationship between ARE and sample sizes and proves that the usual interpretation of the ARE as the ratio of sample sizes holds. Section 4 presents a simulation to study under which conditions and for finite sample sizes, the relationship \( \text{ARE}(Z_s, Z) = (\mu_s/\mu)^2 = n/n_s \) holds where \( n \) and \( n_s \) are the needed sample sizes for \( Z \) and \( Z_s \), respectively, to attain the same power for a given significance level. Section 5 concludes the paper with a discussion.

2. Notation, the logrank test and the asymptotic relative efficiency

2.1. The logrank tests for the relevant and for the composite endpoints

Assume that we have a two-arm study involving random assignment to an active (\( X = 1 \)) or control treatment (\( X = 0 \)) aiming to prove the efficacy of the new active treatment. The effect of treatment is to be evaluated on the time \( T_1^{(j)} \) to a relevant event \( \mathcal{E}_1 \), where the superscript \( j \) indicates the treatment group (\( j = 0 \) for the control group and \( j = 1 \) for the treatment group). Let \( \lambda_1^{(j)}(t) \) denote the hazard function of \( T_1^{(j)} \) (\( j = 0, 1 \)). The null hypothesis of no effect is given by \( H_0: \text{HR}_1(t) = \lambda_1^{(1)}(t)/\lambda_1^{(0)}(t) = 1 \) and the alternative that the new treatment improves survival by \( H_a: \text{HR}_1(t) < 1 \). The logrank test \( Z \) is used to test that the new treatment improves survival.

Assume now that an additional endpoint \( \mathcal{E}_2 \) is considered as component of the primary endpoint and the composite endpoint \( \mathcal{E}_s = \mathcal{E}_1 \cup \mathcal{E}_2 \) is to be used, instead, to prove the efficacy of the new treatment. The effect of treatment would then be evaluated on the time \( T_s^{(j)} \) to \( \mathcal{E}_s \) where \( T_s^{(j)} = \min\{T_1^{(j)}, T_2^{(j)}\} \) and \( T_2^{(j)} \) stands for the time to \( \mathcal{E}_2 \) (\( j = 0, 1 \)). Let \( \lambda_2^{(j)}(t) \) and \( \lambda_s^{(j)}(t) \) denote, respectively, the hazard functions of \( T_2^{(j)} \) and \( T_s^{(j)} \) (\( j = 0, 1 \)). The treatment effect on \( \mathcal{E}_s \) would then be tested with the logrank test \( Z_s \) to compare \( H_0^* : \text{HR}_s(t) = \lambda_s^{(1)}(t)/\lambda_s^{(0)}(t) = 1 \) versus \( H_a^* : \text{HR}_s(t) < 1 \).

Observation of endpoints \( \mathcal{E}_1 \) and \( \mathcal{E}_2 \) depends on whether or not they include a terminating event and yield four different situations referred, in Gómez and Lagakos (2013), as Cases 1, 2, 3 and 4. In this paper we assume that the additional endpoint does not include a terminating event, which corresponds to Case 1 when neither the relevant nor the additional endpoint includes a terminating event, and Case 3, when the relevant endpoint includes a terminating event.

Schoenfeld (1981) studies the asymptotic behaviour of the logrank statistic and proves that under the null hypothesis of no treatment difference, the logrank is asymptotically \( N(0, 1) \) and, under a sequence of alternatives contiguous to the null, the logrank is asymptotically normal with unit variance and finite mean. Gómez and Lagakos apply Schoenfeld’s results and proceed as follows. They consider \( \lambda_1^{(0)}(t) \) as fixed and define a sequence of alternatives \( H_{1,n} \) consisting of instantaneous hazard functions close enough to \( \lambda_1^{(0)}(t) \), for instance taking \( \lambda_{1,n}(t) = \lambda_1^{(0)}(t)e^{g(t)/\sqrt{n}} \) for some \( g(t) \) function. These sequence of alternatives, formulated equivalently as \( \text{HR}_{1,n}(t) = e^{g(t)/\sqrt{n}} \), include pro-
portional hazard alternatives, i.e., taking \( g(t) = \beta \) for a fixed real value \( \beta \). Logrank \( Z \) is asymptotically \( N(0, 1) \) under the null hypothesis of no treatment difference \( H_0 : HR_1(t) = 1 \) and asymptotically normal with unit variance and mean \( \mu \) given in equation (1) under the sequence of alternatives \( H_{a,n} : HR_1(t) = e^{g(t)/\sqrt{n}} < 1 \). Analogously, fix \( \lambda_s(0)(t) \) and define \( H_0^* : HR_s(t) = 1 \) and the sequence of alternatives \( H_{a,n}^* : HR_{s,n}(t) = e^{g_s(t)/\sqrt{n}} < 1 \) for a given function \( g_s(t) \). It follows that \( Z^* \) is asymptotically \( N(0, 1) \) under \( H_0^* \) and asymptotically normal with unit variance and mean \( \mu_s \) given in equation (2) under the sequence \( H_{a,n}^* \). The asymptotic means of \( Z \) and \( Z^* \) are given by

\[
\mu = \frac{\int_0^\infty g(t) p(t)[1 - p(t)]d\Pr_{H_0}(U \geq t)\lambda_1(0)(t)dt}{\sqrt{\int_0^\infty p(t)[1 - p(t)]d\Pr_{H_0}(U \geq t)\lambda_1(0)(t)dt}}, \tag{1}
\]

\[
\mu_s = \frac{\int_0^\infty g_s(t) p_s(t)[1 - p_s(t)]d\Pr_{H_0^*}(U \geq t)\lambda_s(0)(t)dt}{\sqrt{\int_0^\infty p_s(t)[1 - p_s(t)]d\Pr_{H_0^*}(U \geq t)\lambda_s(0)(t)dt}}, \tag{2}
\]

where \( U = \min\{T_1, C\} \) (in Cases 1 and 3) and \( U_s = \min\{T_s, C\} \) denote the observed outcome; \( C \) denotes the censoring time; \( p(t) = \Pr_{H_0}(X = 1 | U \geq t) \) and \( p_s(t) = \Pr_{H_0^*}(X = 1 | U_s \geq t) \) are the null probabilities that someone is at risk at time \( t \) in treatment group 1; \( \Pr_{H_0}(U \geq t) \) and \( \Pr_{H_0^*}(U \geq t) \) are the null probabilities that someone is still at risk at time \( t \) and \( \Pr_{H_0}(U \geq t)\lambda_1(0)(t) \) and \( \Pr_{H_0^*}(U \geq t)\lambda_s(0)(t) \) correspond to the probabilities, under the null hypothesis, of observing events \( \delta_1 \) and \( \delta_s \), respectively, by time \( t \).

### 2.2. Asymptotic relative efficiency

Efficiency calculations throughout the paper will assume that end-of-study censoring at time \( \tau (\tau = 1 \) without loss of generality) is the only non-informative censoring cause for both groups; this assumption indirectly implies that the censoring mechanism is the same for both groups. It is as well assumed that the hazard functions \( \lambda_1^{(j)}(t) \) and \( \lambda_2^{(j)}(t) \) \( (j = 0, 1) \) are proportional, that is, \( HR_1(t) = HR_1 \) and \( HR_2(t) = HR_2 \) for all \( t \), where \( HR_1(t) = \lambda_1^{(1)}(t) / \lambda_1^{(0)}(t) \) and \( HR_2(t) = \lambda_2^{(1)}(t) / \lambda_2^{(0)}(t) \) are the hazard ratios between \( T_1^{(0)} \) and \( T_1^{(1)} \) and between \( T_2^{(0)} \) and \( T_2^{(1)} \), respectively. Note that although we are assuming that the hazard functions \( \lambda_1^{(j)}(t) \) and \( \lambda_2^{(j)}(t) \) \( (j = 0, 1) \) are proportional, this does not imply the proportionality of hazards \( \lambda_1^{(0)}(t) \) and \( \lambda_1^{(1)}(t) \) for the composite endpoint \( T_s \) (see Figure 1).

To assess the difference in efficiency between using logrank test \( Z \), based on the relevant endpoint \( \delta_1 \), and logrank test \( Z_S \), based on the composite endpoint \( \delta_s \), Gómez and Lagakos base their strategy on the behaviour of the asymptotic relative efficiency (ARE) of \( Z_s \) versus \( Z \). The ARE is a measure of the relative power of two tests that can
Figure 1: Survival and hazard ratio for the relevant endpoint (RE), $T_1$, for the additional endpoint (AE), $T_2$ and for the composite endpoint (CE), $T_*=\min\{T_1, T_2\}$. $T_1 \sim$ Weibull with shape parameter $\beta_1 = 2$ (increasing hazard) for treatment groups $0$ and $1$ and $T_2 \sim$ Weibull with shape parameter $\beta_2 = 1$ (constant hazard) for treatment groups $0$ and $1$. Scale parameters for $T_1$ and $T_2$ have been calculated such that $\Pr(T_1 \text{ observed in group } 0) = 0.1$, $\Pr(T_2 \text{ observed in group } 0) = 0.25$, $HR_1 = 0.5$, $HR_2 = 0.9$ and Spearman’s $\rho(T_1, T_2) = 0.45$ assuming Frank’s copula between $T_1$ and $T_2$. Considering the RE as a terminating event (case 3), in this setting $\text{ARE}(Z, Z) = 0.21$.

be interpreted, when the two tests are for the same null and alternative hypothesis, as the ratio of the required sample sizes to detect a specific treatment effect to attain the same power for a given significance level (Lehmann and Romano, 2005). In this case, a value of $\text{ARE} = 0.6$ would mean that we only need 60% as many cases to reach a given power if we use $\mathcal{E}_1$ as we would need if we used $\mathcal{E}_*$. Whenever the tests under consideration, $Z$ and $Z_*$, are asymptotically $N(0, 1)$ under $H_0$ and $H_0^*$, respectively, and asymptotically normal with variance 1 under a sequence of contiguous alternatives to the null hypothesis, a different definition for Pitman’s relative efficiency as the square of the ratio of the non-centrality parameters $\mu$ and $\mu_*$ is appropriate

$$\text{ARE}(Z, Z) = \left(\frac{\mu_*}{\mu}\right)^2,$$

where $\mu$ and $\mu_*$ are to be replaced by expressions (1) and (2).

Before providing the expression that is being used to evaluate the ARE, and for the sake of clarity, we enumerate the assumptions that have been taken into account:

- End-of-study censoring at time $\tau$ is the only non-informative censoring cause for both groups.
- The additional endpoint does not include a terminating event.
• The hazard ratios between \( T_1^{(0)} \) and \( T_1^{(1)} \) and between \( T_2^{(0)} \) and \( T_2^{(1)} \) are proportional, that is, \( \text{HR}_1(t) = \lambda_1^{(1)}(t)/\lambda_1^{(0)}(t) = \text{HR}_1 \) and \( \text{HR}_2(t) = \lambda_2^{(1)}(t)/\lambda_2^{(0)}(t) = \text{HR}_2 \) for all \( t \).

• Effect of treatment on \( \delta_1 \) is tested establishing \( H_0: \text{HR}_1 = 1 \) versus a sequence of alternatives \( H_{a,n}: \lambda_1^{(1)}(t) = \lambda_1^{(0)}(t)e^{g(t)/\sqrt{n}} \) for some \( g(t) \) function. Note that \( g(t)/\sqrt{n} = \log\{\lambda_1^{(1)}(t)/\lambda_1^{(0)}(t)\} \).

• Effect of treatment on \( \delta_2 \) is tested establishing \( H_0^*: \text{HR}_2 = 1 \) versus a sequence of alternatives \( H_{a,n}^*: \lambda_2^{(1)}(t) = e^{g_n(t)/\sqrt{n}} < 1 \) for a given function \( g_n(t) \). Note that \( g_n(t)/\sqrt{n} = \log\{\text{HR}_{a,n}(t)\} \).

Under the above assumptions expression (3) becomes

\[
\text{ARE}(Z, Z) = \left( \frac{\int_0^1 \log\{\lambda_1^{(1)}(t)/\lambda_0^{(0)}(t)\}f_1^{(0)}(t)dt}{\log\{\text{HR}_1\}} \right)^2 \left( \frac{\int_0^1 f_2^{(0)}(t)dt}{\int_0^1 f_1^{(0)}(t)dt} \right)^2,
\]

where \( f_1^{(0)}(t) \) and \( f_2^{(0)}(t) \) are the density functions of \( T_1^{(0)} \) and \( T_2^{(0)} \), respectively.

Remark The density function \( f_2^{(0)}(t) \) is the density of the \( T_2^{(0)} = \min\{T_1^{(0)}, T_2^{(0)}\} \), computed from the joint density between \( T_1^{(0)} \) and \( T_2^{(0)} \), which itself is built from the marginals of \( T_1^{(0)} \) and \( T_2^{(0)} \) by means of a bivariate copula.

3. Relationship between \( \text{ARE} \) and sample sizes

We start establishing that if the hazard ratios for \( T_1^{(j)} (j = 0, 1) \) and for \( T_2^{(j)} (j = 0, 1) \) approach the unity as \( n \) gets large, so does the hazard ratio of the minimum \( T_*^{(j)} \) between \( T_1^{(j)} \) and \( T_2^{(j)} (j = 0, 1) \).

**Lemma 1** Given two sequences of hazard ratios \( \{\text{HR}_{1,n}(t) = \lambda_1^{(1)}(t)/\lambda_1^{(0)}(t)\} \) and \( \{\text{HR}_{2,n}(t) = \lambda_2^{(1)}(t)/\lambda_2^{(0)}(t)\} \), both converging uniformly to 1 as \( n \to \infty \), the sequence corresponding to the hazard ratio of \( T_*^{(j)} = \min\{T_1^{(j)}, T_2^{(j)}\} \), namely \( \{\text{HR}_{*,n}(t) = \lambda_*^{(1)}(t)/\lambda_*^{(0)}(t)\} \), tends to 1 as \( n \to \infty \). In particular, this lemma holds whenever \( \log(\lambda_*^{(1)}(t)/\lambda_*^{(0)}(t)) = O(n^{-1/2}) \), which in turn, is true if \( \log(\lambda_1^{(1)}(t)/\lambda_0^{(0)}(t)) = g_1(t)/\sqrt{n} \) for any bounded real function \( g_1(t) \) \((k = 1, 2)\).

**Proof** It follows immediately that for fixed \( t \), \( \lim_{n \to \infty} \lambda_1^{(1)}(t)/\lambda_1^{(0)}(t) = \lim_{n \to \infty} \lambda_2^{(1)}(t)/\lambda_2^{(0)}(t) = 1 \). Furthermore, it follows that the corresponding densities and
survival functions $f_{1,n}^{(1)}(t)$, $f_{2,n}^{(1)}(t)$, $S_{1,n}^{(1)}(t)$ and $S_{2,n}^{(1)}(t)$, converge to $f_1^{(0)}(t)$, $f_2^{(0)}(t)$, $S_1^{(0)}(t)$ and $S_2^{(0)}(t)$, respectively. Taking into account that the survival function of the minimum, $S_{*n}(t)$ is expressed in terms of the marginal survival functions $S_{1,n}^{(1)}(t)$ and $S_{2,n}^{(1)}(t)$ of $T_1^{(1)}$ and $T_2^{(1)}$ via a copula $C$, that is, $S_{*,n}(t) = C(S_{1,n}^{(1)}(t), S_{2,n}^{(1)}(t))$, it remains to prove that $\lim_{n \to \infty} S_{*,n}(t) = S_{*}^{(0)}(t).$ This result will imply that

$$\lim_{n \to \infty} f_{*,n}^{(1)}(t) = f_*^{(0)}(t), \lim_{n \to \infty} \lambda_{*,n}^{(1)}(t) = \lambda_*^{(0)}(t)$$

and hence the sequence $\text{HR}_{*,n}(t) \to 1$ as $n \to \infty$, as we wanted to prove.

The convergence of $S_{*,n}(t)$ to $S_*^{(0)}(t)$ is guaranteed by the convergence of $S_{1,n}^{(1)}(t)$ and $S_{2,n}^{(1)}(t)$ to $S_1^{(0)}(t)$ and $S_2^{(0)}(t)$, respectively, together with the fact that bivariate copulas $C$ are bivariate distribution functions with uniform marginals. The reader is referred to Lindner and Szimayer (2005) for the corresponding technical proofs. □

**Proposition 1** Consider two test procedures $\phi_n$ and $\phi_*^*$ to test $H_0 : \text{HR}_1(t) = 1$ against $H_{a,n} : \text{HR}_1(t) < 1$ and $H_0^* : \text{HR}_n(t) = 1$ against $H_{a,n}^* : \text{HR}_n(t) < 1$, respectively. Let $n$ and $n_*$ be the sample sizes required for $\phi_n$ and $\phi_*^*$, respectively, to have power at least $\Pi$ at level $\alpha$. Assume the sequences $\phi = \{\phi_n\}$ and $\phi^* = \{\phi_*^n\}$ are based on the logrank statistics $Z$ and $Z^*$, respectively, converging to Normal $\mu$ and Normal $\mu_*$, with $\mu$ and $\mu_*$ given in (1) and (2), under sequences of local alternatives $\text{HR}_{k,n}(t)$ ($k = 1, 2$) converging uniformly to 1 as $n \to \infty$. Given $0 < \alpha < \Pi < 1$,

$$\lim_{\text{HR}_{1,n}(t) \to 1} \frac{n}{n_*} = \text{ARE}(Z_*, Z).$$

The usual interpretation of the ARE as the reciprocal ratio of the sample sizes holds even when two different sets of hypotheses ($H_0$ versus $H_{a,n}$ and $H_0^*$ versus $H_{a,n}^*$) are tested. As a consequence of this proposition, the interpretation of the ARE is the following. If $\text{ARE}(Z_*, Z) = 0.7$, then, asymptotically, we only need 70% as many cases to attain a given power if we use $Z$ as we would need if we used $Z_*$. 

**Proof 2** By Lemma 1, uniform convergence to 1 of $\{\text{HR}_{1,n}(t)\}$ and $\{\text{HR}_{2,n}(t)\}$ imply that $\lim \text{HR}_{*,n}(t) \to 1$. Under the sequence of contiguous alternatives to the null $H_{a,n} : \{\text{HR}_{1,n}(t) = \lambda_{1,n}^{(1)}(t)/\lambda_{1,n}^{(0)}(t)\} \to 1$ and $H_{a,n}^* : \{\text{HR}_{*,n}(t) = \lambda_{*,n}^{(1)}(t)/\lambda_{*,n}^{(0)}(t)\} \to 1$, both $Z$ and $Z^*$ are asymptotically $N(\mu, 1)$ and $N(\mu_*, 1)$, respectively. The power function for a one-sided test with size $\alpha$ is therefore given, respectively, by

$$\Pi_1 = \lim_{n \to \infty} \text{Prob}\{Z < z_{1-\alpha} | H_{a,n}\} = 1 - \Phi(-z_{1-\alpha} + \mu)$$

$$\Pi_* = \lim_{n \to \infty} \text{Prob}\{Z_* < z_{1-\alpha} | H_{a,n}^*\} = 1 - \Phi(-z_{1-\alpha} + \mu_*)$$

(5)
where $\Phi$ is the distribution function of the standard normal and $z_{1-\alpha}$ is the standard normal quantile corresponding to the left tail probability $\alpha$. It immediately follows that $\Pi_1 = \Pi_0$ is equivalent to $\mu = \mu_*$.  

The equivalence of powers ($\Pi_1 = \Pi_0$) implies that $\mu = \mu_*$, given by (1) and (2). Equivalently

$$\left( \frac{\mu_*}{\mu} \right)^2 = 1 \iff \left( \frac{\int_0^\tau g(t)p(t)[1-p(t)]\Pr_{H_0}[U \geq t]\lambda_1^{(0)}(t)dt}{\sqrt{\int_0^\tau g(t)p(t)[1-p(t)]\Pr_{H_0}[U \geq t]\lambda_1^{(0)}(t)dt}} \right)^2 = 1. \quad (6)$$

Since

$$p(t) = \frac{\Pr_{H_0}\{U \geq t \mid X = 1\} \pi}{\Pr_{H_0}\{U \geq t\}} = \frac{\Pr_{H_0}\{U^{(j)} \geq t\} \pi}{\Pr_{H_0}\{U \geq t\}},$$

where $\pi = \Pr_{H_0}\{X = 1\}$, we have

$$p(t)(1-p(t))\Pr_{H_0}\{U \geq t\} = \frac{\Pr_{H_0}\{U^{(1)} \geq t\} \pi \Pr_{H_0}\{U^{(0)} \geq t\} (1-\pi)}{\Pr_{H_0}\{U^{(0)} \geq t\}} + \Pr_{H_0}\{U^{(1)} \geq t\} \pi.$$

Based on the stated assumptions, because $T_1^{(j)}$ is right-censored by the end-of-study at time $\tau$, and under the null hypothesis of no effect ($S_1^{(0)}(t) = S_1^{(1)}(t)$), we have $\Pr_{H_0}\{U^{(j)} \geq t\} = S_1^{(0)}(t)1([0,1])1(t)$, for $j = 0, 1$. Replacing in (1), the noncentrality parameter $\mu$ becomes

$$\mu = \frac{\sqrt{\pi(1-\pi)} \int_0^\tau g(t)S_1^{(0)}(t)\lambda_1^{(0)}(t)dt}{\int_0^\tau S_1^{(0)}(t)\lambda_1^{(0)}(t)dt} = \frac{\sqrt{\pi(1-\pi)} \int_0^\tau g(t)f_1^{(0)}(t)dt}{\int_0^\tau f_1^{(0)}(t)dt}$$

where $f_1^{(0)}(t)$ is the marginal density function for $T_1^{(0)}$. Analogously, it can be seen that

$$\mu_* = \frac{\sqrt{\pi(1-\pi)} \int_0^\tau g_*(t)f_*(t)dt}{\int_0^\tau f_*(t)dt}$$

where $f_*(t)$ is the density function for $T_1^{(0)}$. The reader is addressed to the online supporting material of Gómez and Lagakos paper for other technical details.
If we would replace $g(t)$ and $g_e(t)$ by $\sqrt{n} \log \left( \frac{\lambda^{(1)}_n(t)}{\lambda_n^{(0)}(t)} \right) = \sqrt{n} \log(HR_1)$ and $\sqrt{n} \log \left( \frac{\lambda^{(1)}_n(t)}{\lambda_n^{(0)}(t)} \right)$, respectively, equality (6), after cancelling $\pi_1(1 - \pi_1)$, becomes equal to

$$\lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{\int_0^1 \log \left( \frac{\lambda^{(1)}_n(t)}{\lambda_n^{(0)}(t)} \right) f_n(0)(t)dt}{\sqrt{2} \log(HR_1) \sqrt{\int_0^1 f_n(0)(t)dt}} = 1$$

which in turn is equivalent to

$$\lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{n}{n \to 1,n \to 1} \frac{\left( \int_0^1 \log \left( \frac{\lambda^{(1)}_n(t)}{\lambda_n^{(0)}(t)} \right) f_n(0)(t)dt \right)^2}{(\log(HR_1))^2 \left( \int_0^1 f_n(0)(t)dt \right)^2} \approx \lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{n \left( \int_0^1 f_n(0)(t)dt \right)}{n \to 1,n \to 1} \approx \frac{\text{expected number } \delta_1}{\text{expected number } \delta_1}$$

and it follows that $\text{ARE}(Z_n,Z) = \lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{n}{n \to 1,n \to 1}$, as we wanted to prove. □

Note that (7) implies

$$\frac{\left( \int_0^1 \log \left( \frac{\lambda^{(1)}_n(t)}{\lambda_n^{(0)}(t)} \right) f_n(0)(t)dt \right)^2}{(\log(HR_1))^2 \left( \int_0^1 f_n(0)(t)dt \right)^2} = \lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{n \left( \int_0^1 f_n(0)(t)dt \right)}{n \to 1,n \to 1} \approx \frac{\text{expected number } \delta_1}{\text{expected number } \delta_1}$$

and whenever $\lambda^{(1)}_n(t)/\lambda_n^{(0)}(t)$ is approximately constant and equal to $HR_1$, we would have

$$\frac{\left( \frac{1}{\log(HR_1)} \right)^2}{\left( \frac{1}{\log(HR_1)} \right)^2} = \lim_{HR_{1,n}(t) \to 1,n \to 1} \frac{n \left( \int_0^1 f_n(0)(t)dt \right)}{n \to 1,n \to 1} \approx \frac{\text{expected number } \delta_1}{\text{expected number } \delta_1}$$

4. Simulation

4.1. Simulation

Our next aim is to simulate data to empirically check how close we are to the limiting relationship $n/n_s = \text{ARE}(Z_n,Z)$ when $\Pi_1 = \Pi_s$ for different finite sample sizes. To
The asymptotic relative efficiency and the ratio of sample sizes when testing...

Conduct the simulations we will assume, as Gómez and Lagakos did, that \( T_1^{(j)} \) and \( T_2^{(j)} \) follow Weibull distributions. Weibull distributions are chosen for their wide use in the field of survival analysis due to its flexibility, allowing decreasing, constant and increasing hazard rates. The corresponding shape and scale parameters are denoted by \( \beta_k \) and \( b_k^{(j)} \) \((j = 0, 1, k = 1, 2)\) (shape parameters for both groups are taken equal so that the assumption of the proportionality of the hazard ratios holds). To establish the bivariate distribution of \((T_1^{(0)}, T_2^{(0)})\) we consider Frank’s Archimedean survival copula, again as Gómez and Lagakos did. Other choices of copulas would be possible, although main conclusions and recommendations will not differ (Plana-Ripoll and Gómez, 2014). Frank’s copula depends on an association parameter \( \theta \) between \( T_1^{(0)} \) and \( T_2^{(0)} \) which is biunivocally related to Spearman’s rank correlation \( \rho \). Different scenarios will be simulated according to several choices of \((\beta_1, \beta_2, p_1^{(0)}, p_2^{(0)}, HR_1, HR_2, \rho)\) where \( p_1^{(0)} \) and \( p_2^{(0)} \) are the probability of observing events \( E_1 \) and \( E_2 \), respectively, for treatment group 0, \( HR_1 \) and \( HR_2 \) are relative treatment hazard ratios for \( T_1^{(j)} \) versus \( T_2^{(0)} \) \((j = 1, 2, \text{ respectively})\) and \( \rho \) is Spearman’s rank correlation between \( T_1^{(0)} \) and \( T_2^{(0)} \).

Given a set of values for \((\beta_1, \beta_2, p_1^{(0)}, p_2^{(0)}, HR_1, HR_2, \rho)\), for a given power \( \Pi \) and a significance level \( \alpha \), the simulation steps are the following:

1. **Computations for the relevant endpoint \( E_1 \).** The scale parameters \( b_1^{(0)} \) and \( b_1^{(1)} \) and the probability \( p_1^{(1)} \) of observing the relevant endpoint in group 1 are derived as:

\[
b_1^{(0)} = \frac{1}{(-\log(1 - p_1^{(0)}))^{1/\beta_1}}
\]

\[
b_1^{(1)} = \frac{b_1^{(0)}}{HR_1^{(1/\beta_1)}}
\]

\[
p_1^{(1)} = 1 - e^{-(1/b_1^{(1)})\beta_1}
\]

2. **Computations for the additional endpoint \( E_2 \).** The scale parameters \( b_2^{(0)} \) and \( b_2^{(1)} \) and the probability \( p_2^{(1)} \) of observing the additional endpoint in group 1 are derived as:

\[
b_2^{(0)} = \begin{cases} 
\frac{1}{(-\log(1 - p_2^{(0)}))^{1/\beta_2}} & \text{for Case 1} \\
* & \text{for Case 3}
\end{cases}
\]

\[
b_2^{(1)} = \frac{b_2^{(0)}}{HR_2^{(1/\beta_2)}}
\]

\[
p_2^{(1)} = 1 - e^{-(1/b_2^{(1)})\beta_2}
\]
3. Computation of sample sizes \( n \) and \( n_s \)

(a) Compute \( n \) (per group) following Freedman (1982) formulas as follows

\[
n = \frac{E}{p_1^{(0)} + p_1^{(1)}} \tag{8}
\]

where

\[
E = \frac{(HR_1 + 1)^2(z_{1-\alpha} + z_{1})^2}{(HR_1 - 1)^2} \tag{9}
\]

(b) Compute ARE\( (Z_s, Z) \) based on \( (\beta_1, \beta_2, p_1^{(0)}, p_2^{(0)}, HR_1, HR_2, \rho) \).

(c) Compute \( n_s = n / \text{ARE}(Z_s, Z) \).

(d) Compute \( N = \max\{n, n_s\} \).

4. Simulation of \( T_1^{(0)}, T_1^{(1)}, T_2^{(0)}, T_2^{(1)}, T_3^{(0)}, T_3^{(1)} \)

Simulate 1000 samples of size \( N \) for the 4 endpoints \( T_k^{(j)} \) from Weibull \( (b_k^{(j)}, \beta_k) \) \((j = 0, 1, k = 1, 2)\). Compute \( T_s^{(j)} = \min\{T_1^{(j)}, T_2^{(j)}\} \).

5. Computation of empirical powers \( \hat{\Pi}_1 \) and \( \hat{\Pi}_s \)

For each sample of size \( n \) \((n_s)\), compute the logrank statistic \( Z \) \((Z_s)\) to compare the treatment effect between \( T_1^{(0)} \) and \( T_1^{(1)} \) \((T_s^{(0)} \) and \( T_s^{(1)} \). For a given significance level \( \alpha \), the rejection region comprises all observed \( Z \) \((Z_s)\) such that \( Z < z_{1-\alpha} \) \((Z_s < z_{1-\alpha})\). The empirical powers, denoted by \( \hat{\Pi}_1 \) \((\hat{\Pi}_s)\), are calculated as the proportion of samples for which \( Z < z_{1-\alpha} \) \((Z_s < z_{1-\alpha})\).

We note here that whenever \( n_s < n \), we only use, for each sample, the first \( n_s \) simulated values to compute \( \hat{\Pi}_s \), while when \( n < n_s \), we only use the first \( n \) simulated values to compute \( \hat{\Pi}_1 \).

6. Comparison between \( \hat{\Pi}_1 \) and \( \hat{\Pi}_s \)

For each scenario \( (\beta_1, \beta_2, p_1^{(0)}, p_2^{(0)}, HR_1, HR_2, \rho) \), we compare the differences between the two empirical powers \( \hat{\Pi}_1 \) and \( \hat{\Pi}_s \), obtained from the 1000 simulations.
The asymptotic relative efficiency and the ratio of sample sizes when testing...

Table 1: Values of parameters $\beta_1$, $\beta_2$, $p_1$, $p_2$, HR$_1$, HR$_2$ and $\rho$ used for the simulations. There are 624 different configurations, excluding those yielding sample sizes larger than 1100 and $\text{ARE}(Z^*, Z) > 10$.

4.2. Results

We have set $\Pi = 0.9$ and $\alpha = 0.05$ (other values would not provide additional information). We have chosen meaningful values for $(\beta_1, \beta_2, p_1^{(0)}, p_2^{(0)}, \text{HR}_1, \text{HR}_2, \rho)$, based on those arising in cardiovascular clinical trials (Gómez, Gómez-Mateu, Dafni, 2014) (see Table 1). We restrict our simulation study to 624 scenarios corresponding to $\text{ARE}(Z^*, Z) \leq 10$ and sample sizes smaller than 1100 patients per group. These scenarios yield $\text{ARE}(Z^*, Z)$ values between 0.20 and 9.93, sample sizes, $n$, for the relevant endpoint between 142 and 1081, and, $n^*$, for the composite endpoint between 53 and 1077 (see Table 2). Similar results were obtained for Case 1, when neither the relevant nor the additional endpoint includes a terminating event, and for Case 3 when the relevant endpoint includes a terminating event, and we only discuss here Case 1.

Table 2: Computed values of $n$, $n^*$, and $\text{ARE}(Z^*, Z)$ in step 3 of the simulation based on the parameter values given in Table 1.

The empirical powers $\hat{\Pi}_1$ in our simulation study resulted in powers between 0.87 and 0.94, with a median of 0.91. A slightly higher median was found for scenarios with low hazard ratios. This finding is acknowledged as well by Freedman (1982).

Table 3 provides the percentiles for the absolute value differences between $\hat{\Pi}_1$ and $\hat{\Pi}_1$. We observe that in 75% of the cases the difference is smaller than 2.3%, and among cases with $\text{ARE}$ as large as 3 the difference shrinks to 1.9%. There are, however, few instances, where this difference can be as large as 6%, and they deserve a closer look.

Figure 2 plots the differences $\hat{\Pi}_* - \hat{\Pi}_1$ as a function of the ARE($Z_*,Z$) values. The behaviour is remarkably different when ARE($Z_*,Z$) ≤ 3 or ARE($Z_*,Z$) > 3. Whenever ARE($Z_*,Z$) ≤ 3, $\hat{\Pi}_*$ fluctuates around $\hat{\Pi}_1$, within a range of 4%. However, when ARE($Z_*,Z$) > 3, corresponding mostly to scenarios where treatment has a stronger effect on the additional endpoint than on the relevant endpoint (HR$_2$ ≤ HR$_1$ − 0.2) and the anticipated number of events in the control group is larger for the additional endpoint than for the relevant (p$_2^{(0)}$ ≥ p$_1^{(0)}$), the empirical power $\hat{\Pi}_*$ of the logrank test based on the CE never achieves the same power as the logrank test for the relevant endpoint would get. In these cases the interpretation of the ARE($Z_*,Z$) as the ratio of the sample sizes, $n/n_*$, is not as straightforward. Nevertheless, this does not mean that the recommendation of using the CE does not have to be followed since larger values for $n_*$ needed to attain the same power as $n$ does, would reduce the ARE value but not as much as to cross the “1” border that would imply to use the relevant endpoint instead of the CE.

Figure 2: Differences between empirical powers $\hat{\Pi}_* - \hat{\Pi}_1$ as function of ARE($Z_*,Z$) and in terms of HR$_2$ − HR$_1$. 

$0.001 ≤ HR_2 − HR_1 ≤ 0.1$

$HR_2 − HR_1 ≥ 0.2$

$HR_2 − HR_1 ≤ -0.2$
If we analyze the differences between $\hat{\Pi}_s$ and $\hat{\Pi}_1$ as a function of the differences between the two hazard ratios ($HR_2 - HR_1$), we observe that when the two hazard ratios are very close, the two empirical powers are very close. Whenever $HR_2 - HR_1 \leq -0.2$, not only ARE$(Z_s, Z)$ values tend to be higher, but also $\hat{\Pi}_s < \hat{\Pi}_1$. (see Figure 2).

Taking into account that absolute differences between powers smaller than 5% could be considered irrelevant, we conclude that the asymptotic relationship $ARE(Z_s, Z) = n/n_s$ is valid in the majority of scenarios.

All computations in this paper have been implemented in R and are available on request to either author.

5. Discussion

Pitman’s relative efficiency is defined as the limiting ratio of sample sizes to give the same asymptotic power under sequences of local alternatives. Given two asymptotically standard normal tests $S_n$ and $T_m$ under the same null and alternative hypotheses, the alternative definition $ARE = (\mu_S/\mu_T)^2$ where $\sqrt{n}\mu_S$ and $\sqrt{m}\mu_T$ are the respective means under local alternatives, can be used because the equality of the powers holds if $m = (\mu_S/\mu_T)^2$.

Gómez and Lagakos’ method uses the alternative definition of ARE to develop all the computations for the two corresponding logrank tests. Our goal has been to check that the relationship between $(\mu_S/\mu_T)^2$ and the ratio of sample sizes still held when the two hypotheses under test were not the same ($H_0$ versus $H_a$ and $H_0^*$ versus $H_a^*$).

It is important to keep in mind that these two hypotheses tests are by no means equivalent, for instance, to check whether treatment has a beneficial effect, we might use $\mathcal{E}_1$ or we might add endpoint $\mathcal{E}_2$ and use $\mathcal{E}_s$. As it is shown in Gómez (2011), even if we assume that the times to $\mathcal{E}_1$ and to $\mathcal{E}_2$ are independent, a beneficial effect on $\mathcal{E}_s$ can occur simultaneously with a beneficial effect on $\mathcal{E}_1$ and a harmful effect on $\mathcal{E}_2$ and not finding a beneficial effect on the composite event $\mathcal{E}_s$ is no guarantee of not having some effect on the individual events $\mathcal{E}_1$ or $\mathcal{E}_2$.

The main result of this paper proves that ARE$(Z_s, Z)$ coincides with $n/n_s$, being $n$ and $n_s$ the sample sizes needed to detect specific alternatives $HR_1$ and $HR_2$ to attain power $\Pi$ and for the same significance level $\alpha$. Therefore, we can use and interpret ARE in its usual way.

The simulation study has been conducted in such a way that for fixed values $n$ and ARE$(Z_s, Z)$, the sample size $n_s$ is calculated as $n_s = n/ARE(Z_s, Z)$. Hence an approximate equality of the empirical powers $\hat{\Pi}_1$, of logrank test $Z$ for $H_0$ versus $H_{a,n}$, and of $\hat{\Pi}_s$ of logrank test $Z_s$ for $H_0^*$ versus $H_{a,n}^*$, indicates that the relationship $ARE(Z_s, Z) = n/n_s$ holds. Main results from our simulations show that the absolute differences between $\hat{\Pi}_1$ and $\hat{\Pi}_s$ are most of the times less than 2.5%, hence the usual interpretation between $(n, n_s)$ and $ARE(Z_s, Z)$ holds for finite sample sizes.
For those scenarios under which \( \text{ARE}(Z_*, Z) > 3 \), we observe that the empirical power of the test based on \( \delta_* \) never achieves the empirical power that the logrank test based on \( \delta_1 \) would get. Consequently, larger values of \( n_* \) would be needed to attain the same power as \( n \) does. In these instances, even though the relationship \( \text{ARE}(Z_*, Z) = n/n_* \) is not necessarily true, the recommendation to use the composite endpoint \( \delta_* \) instead of the relevant endpoint \( \delta_1 \) will still be valid because very rarely a value of \( \text{ARE}(Z_*, Z) > 3 \) would go down to less than 1. However, caution will be needed if one wants to use the relationship \( \text{ARE}(Z_*, Z) = n/n_* \) to compute the required sample size \( n_* \) if \( \text{ARE}(Z_*, Z) > 3 \). In these cases, a different formulation should be seek.
