#### Abstract

The intercity bus market in Spain operates under a competition for the market system, granting a monopolistic concession to a company that functions without public assistance on various lines. Since some of them are profitable and other are loss-making, the operating firm runs assuming implicitly an internal cross-subsidization system, which ends up hurting lower income citizens. This study formalizes and solves the economic model of cross-subsidies, using bus demand data for the Madrid-Irun route to calculate the exact amount of profits used as subsidies for each line. Despite operating costs preventing profitability on some lines, the company's overall profits are positive and significant, indicating a failure of the current bidding system to promote fair competition. While liberalization could reduce prices, it does not ensure service continuity on unprofitable lines. An alternative approach would be the provision of direct subsidies to ensure connectivity. The study also estimates potential changes in demand and consumer surplus with liberalization. By highlighting the problems of the current crosssubsidization system and analyzing a proposal for liberalization with direct subsidies, this research addresses the reform needs of the Spanish intercity bus system.

## 1. Introduction

Transportation is a fundamental aspect of modern society, allowing for the connection between different places and the mobility of people and goods, which is essential for the economy and social development: it improves people's accessibility to services and opportunities such as work, education, healthcare, etc. One of the most pressing issues in the field of transportation economics is the provision of public transportation as a necessity for individuals who do not have access to private vehicles, as well as a more environmentally sustainable travel alternative. With the increasing demand for transportation services, it is crucial to improve the efficiency and sustainability of the system. The aim of this TFG is to investigate the bus transportation system in interurban areas, currently characterized by cross-subsidization mechanisms, and explore potential strategies to enhance their performance.

The current bidding system that distributes the different routes in which interurban buses operate in Spain grants a monopolistic contract of the route to the winning company for a certain amount of time. As a result, the company establishes an internal system of crosssubsidies, which involve using profits from profitable lines (the ones with higher levels of demand/or lower operation costs) to cover losses from unprofitable lines (with low demand and/or higher costs). However, this approach is subject to criticism from both economic and social perspectives as it can lead to inefficient allocation of resources and also have a regressive impact, since most of the bus users belong to the lower parts of the income distribution.

In a European context of liberalization of the interurban transport market, and with a Spanish law expressing intentions to follow the example of our neighbors on the horizon, it is important to open the debate on the current impact of the cross-subsidy mechanism, which manages to sustain bus connection services despite the unsustainability of some of the lines. It is necessary for the economy to reconsider its current impact and evaluate the alternatives we have as a country, once the market is liberalized, in order to maintain the service on those unprofitable lines that predominantly connect rural low-density areas and ensure affordable mobility for the entire population.

In order to develop the work, the following research questions will guide the investigation:

- What is the context that explains the current intercity bus system in Spain?
- How does the mechanism of cross-subsidies work? How does it relate to transportation demand and various restrictions, whether from the government or the company, and cost?
- What is the empirical reality? What is the impact of costs on the profitability of transportation providers?
- What effect does this cross-subsidy system have on the population? What alternatives can be proposed and what impact would they have?

There is limited economic literature analyzing the system of cross-subsidies, and even less specialized in the transportation system, making this a novel project that aims to fill an existing knowledge gap. Research studies such as the one conducted by Asensio and Matas (2023), which analyze interurban road transport in Spain, or the study on crosssubsidies in the postal service by Cremer et al. (1997), will serve as guides and references for this work.

Regarding the methodology, a combination of theoretical and empirical methods will be used in the study to obtain and analyze the outcomes of the cross-subsidy system. Firstly, a simple partial equilibrium model will be developed to characterize the equilibrium under the assumption that each line belonging to the route represents a market. The objective is to understand the mathematical process that leads to the market allocation of the price of the ticket and number of bus users, as well as to try to understand how the subsidies are calculated. Once the economic model is solved, we will proceed with its empirical application. Based on the observed bus demand database for one of the routes (route 157, belonging to Madrid-Irún), which presents real data for some of the variables involved in the model, and using approximate calculations for the remaining ones, we will use R studio software to determine the values of all the unknowns and be able to solve the problem. We will also use this programming language to estimate the
profitability of each line as well as to simulate the new demand, economic costs and impact on consumer's surplus of an alternative to the cross-subsidy system.

The remaining of the work is structured as follows. After this introduction, section 2 provides context of the interurban bus market situation through a literature review of the key concepts and previous background. Section 3 includes the formalization of the microeconomic model and its solving under different market situations. On section 4 the model is applied empirically, including explanations about the nature of the data used, our approach, and an analysis of the results. Section 5 explains the scenario of liberalization and its possible impacts on the structure and outcomes of the interurban bus market. Finally, in section 6 is proposed an alternative system and calculated its potential results in terms of demand increase, resources needed and consumer surplus variation. A final section of conclusions analyzes the main implications of the results obtained.

In conclusion, this study aims to shed light on unexplored aspects of the topic, providing valuable insights for future research and policy considerations.

## 2. Spain's intercity bus system

### 2.1. Importance of the bus in Spain

With a wide coverage of the national territory, intercity bus companies offer regular services connecting the main Spanish cities, as well as rural and remote areas that are often frequent in the country. This transportation market, which has a greater weight than in most European countries, was used by 206 million people in 2019, of which 30 belong to the state network of regular intercity buses (the subject of study of this work), according to Asensio and Matas (2023). Interurban bus transportation represents an economic and practical alternative to other means, such as airplanes or trains, which have a lesser weight in the Spanish transportation system. Among other things, this difference in weight is due to the fact that, contrary to what happened in other countries, interurban corridors were not reserved for trains (Van de Velde, 2014), and to a greater investment in road infrastructure until the expansion of high-speed rail. Therefore, the importance of buses in Spain is enormous, as it is the main mean of transportation for medium and longdistance passengers.

### 2.2. Regulation and outcomes

Currently, the intercity bus market in Spain is not liberalized, unlike the rest of Europe. While in other countries a "competition in the market" system has been advocated, in which companies compete with each other for their share of the market, trying to differentiate themselves from others either through price or service quality to gain a larger share of passengers, Spain has chosen a regulation in the form of "competition for the market". This system is characterized by companies competing for the exclusive operation of services for 20 years.

The Ley de Ordenación del Transporte Terrestre (1987) considers intercity bus service as a public service that will be offered under a competitive bidding system. Based on a regulatory framework, companies submit their proposals for operation to the competent authority, which in this case would be the Ministerio de Transporte (MITMA), with the hope of obtaining the concession or contract that allows them to operate the bus service in a monopolistic manner for a certain period of time. This proposal is conditioned by the
so-called "pliegos", which are the variables specified by MITMA that are taken into account in each bidding process. Some of these evaluation criteria, which have varied over time, are price, frequency, safety, and vehicle quality and comfort. Each criterion is assigned a different weight, and the company that wants to win the bid must submit a proposal with a higher score than the others. However, in 2007 (when the contracts that had been extended to bus companies with the creation of the LOTT were about to expire), the pliegos were declared by the Comisión Nacional de la Competencia as anticompetitive. As a result, since then, elements that are contrary to competition have been eliminated from the bidding process, increasing the probability of a company participating in the bidding process and thus the number of bidders. Over the years, the importance of the two main competition variables, prices and frequency, has increased, but the comparison with intercity bus markets in other countries shows that liberalization (i.e., competition in the market) leads to lower prices and a better service adapted to demand. It is no coincidence that passengers on Spanish buses pay $88 \%$ more than French or Italian passengers, $41 \%$ more than Portuguese passengers, $36 \%$ more than German passengers, or $28 \%$ more than bus passengers in the UK (Asensio and Matas, 2023). Therefore, while the concession system could result in price and frequency combinations similar to those of a liberalized market, the defining structure of the Spanish market's bids has not yet achieved it.

### 2.3. Cross subsidies system

A crucial feature of concessions is that they are granted by routes, although a single route may (and often does) include more than one line.

We understand a route as a set of geographically nearby lines (e.g. Madrid-Irun). In contrast, a line refers to the sum of services operated by the company via bus, which follow a predefined and scheduled route to transport passengers from one origin to one destination (with internal stops), thus forming the entirety of the route. For example, the Madrid-Burgos, Burgos-Santander, or Bilbao-Madrid lines are part of the Madrid-Irun route. Services are equivalent to the frequencies at which the bus starts the route of the line, and they vary depending on how commercial the line is, as well as expeditions, which is the number of buses that leave on each service.

Once the key concepts relevant to our work have been defined, we can continue to explain the nature of concessions. The company that wins the tender operate the route without any direct economic support from the state, that is, without any type of direct subsidy. Moreover, the price per unit of distance $(€ / \mathrm{km})$ offered must be the same for all the lines. Within the same route, we can find commercial lines with high demand because they connect strategic cities, either due to their demographic or economic importance, as well as unprofitable routes, which generally offer services in rural territories with low population density and/or more mountainous or inaccessible areas. This polarity between the lines and the fact that the company operates at its own risk and fortune leads to the implicit implementation of an internal cross-subsidy system. Firm operate in profitable lines, which have higher profitability due to operating costs being lower than the price set during the competition for the route, but since the company is contractually obligated to operate all lines of the route regardless of their profitability, the profits of these lines are internally redistributed to cover the losses of the loss-making lines, where costs exceed the price. Cremer et al (1997) make a study of the cross subsidies in the postal sector, where they point out that if the operator had freedom to set its price to cover costs, service would be provided to all potential customers, but given the restriction of uniform prices (to make it "affordable"), they are likely to be below cost for some consumer types.

This system of cross-subsidies, like practically everything in economics, has its advantages and disadvantages.

On the one hand, since the government stays out of it, offering a service (on some lines) at a price below cost does not result in an increase in public spending, as direct subsidies from the state would. Additionally, the state ensures a service on lines that would not be possible with a total liberalization of the system, due to a lack of commercial appeal. Later on, we will evaluate this liberalization and its possible alternatives to ensure territorial connectivity.

However, the system of cross-subsidies results in significant welfare losses. Users of profitable lines face a bus ticket price higher than the cost, contrary to what would happen in a situation of perfect competition. This ends up causing the current system to have a significant regressive impact on the population, since regular bus users, who bear most of the costs, are mainly low-income citizens or students who do not have a private vehicle as an alternative. Additionally, as Asensio and Matas (2023) explain, buses face difficulties competing with other modes that do not have to bear the costs arising from
the cross-subsidy system in profitable areas. It should also not be forgotten that since the characteristics of the itineraries are decided by the government, this is a rigid system in terms of adapting to changes in demand, creating new routes, or taking advantage of new technologies.

Overall, the impact of the cross-subsidy system on the public transport model and the population, and more specifically its lower strata, obliges us to study its economic functioning and impacts, as we will proceed to do next.

## 3. The microeconomic model

By formalizing the cross subsidies system into a mathematical model we intend to understand the intuition about the relation between variables such as price, quantity of consumers and costs. One may think on another crucial variable involved on the bus system, the frequencies of the buses, which are one of the points defined and inspected on the bus tenders. For the seek of simplicity, in this work we are going to keep the variable of frequencies out of the equations, and implicitly assume their no-variation. Next, you will find the solving of a simple partial equilibrium model that characterize the equilibrium of the market under different competing circumstances.

### 3.1. The model under perfect competition

The variables:
c is the marginal cost of the bus line, in km terms
$\boldsymbol{p}$ is the price/km paid by the consumer
$\boldsymbol{q}$ is the number of passangers-km to whom the service is provided
$\boldsymbol{p}=\boldsymbol{\alpha}-\boldsymbol{\beta} \boldsymbol{q}$ is the consumers inverse demand function
$\boldsymbol{\alpha}$ is the maximum price the consumers are willing to pay
$\boldsymbol{\beta}$ is the slope of the consumers inverse demand function
We assume that:

- We are in perfect competition, such that $\mathrm{p}=\mathrm{mc}$
- Marginal cost is the only cost, and it is constant ( $\mathrm{mc}=\mathrm{c}$ )
- $\boldsymbol{\alpha}, \boldsymbol{\beta}$ and $\boldsymbol{c}$ are exogenous variables

Then, the mathematical resolution of the problem in perfect competition is:

$$
p=c
$$

$$
\begin{aligned}
& p=\alpha-\beta q \\
& c=\alpha-\beta q
\end{aligned}
$$

$$
p *=c, \quad q *=\frac{\alpha-c}{\beta}
$$

Where $\boldsymbol{p} * \boldsymbol{a n d} \boldsymbol{q} * \quad$ are the equilibrium price and quantity.

The perfect competition graphical representation of situation in which there are 2 lines operated independently, idexed by $j=1,2$, where 1 represents a line with low costs and 2 the one with high costs, would be as:

Low-cost line

High-cost line

### 3.2. The cross subsidies model

Given a situation in which an intercity bus company wins a tender to operate a route in which there are profitable lines with costs being lower than competitive market price (in market equilibrium $\mathrm{p}=\mathrm{mc}$ ), and also unprofitable lines with costs being higher than market prices, a cross subsidies mechanism is implicitly applied. We describe it as follows:

### 3.2.1. Assuming linear demand functions

$\boldsymbol{p}_{1}=\boldsymbol{\alpha}_{1}-\boldsymbol{\beta}_{\mathbf{1}} \boldsymbol{q}_{\mathbf{1}} \quad$ is the consumers inverse demand function for the line with prices higher than costs, we will call it the "Profitable line (1)"
$\boldsymbol{p}_{\mathbf{2}}=\boldsymbol{\alpha}_{\mathbf{2}}-\boldsymbol{\beta}_{\mathbf{2}} \boldsymbol{q}_{\mathbf{2}} \quad$ is the consumers inverse demand function for the line with costs higher than prices, we will call it the "Loss-making line (2)"
$\boldsymbol{p}_{1}$ and $\boldsymbol{p}_{2}$ are the price/km paid by a consumer for the Profitable and Loss-making line, respectively
$\boldsymbol{q}_{1}$ and $\boldsymbol{q}_{\mathbf{2}}$ are the passengers-km of the Profitable and Loss-making line, respectively $\alpha_{1}$ and $\alpha_{2}$ are the maximum price the consumers are willing to pay on the profitable and loss-making line, respectively
$\boldsymbol{\beta}_{\mathbf{1}}$ and $\boldsymbol{\beta}_{\mathbf{2}}$ are the slope of the inverse demand functions of the Profitable line and Loss-making line

## Assumptions

- Marginal cost is the only cost, and it is constant in both rutes ( $\mathrm{mc}=\mathrm{c}$ ), and described as $\boldsymbol{c}_{\mathbf{1}}$ and $\boldsymbol{c}_{\mathbf{2}}$ (costs of vehicle/km from the Profitable and Loss-making line)
- $\alpha_{1,2}, \beta_{1,2}$ and $\boldsymbol{c}_{1,2}$ are exogenous variables

## Restrictions

The government imposes a restriction as to ensure that prices are the same in both lines and that there is no difference between consumers pays.

$$
p_{1}=p_{2}
$$

The intercity bus company self-imposes another restriction, a profitability restriction, by which the total revenue perceived by the two lines has to be at least equal to the total cost of providing services in both lines.

$$
p_{1} q_{1}+p_{2} q_{2} \geq c_{1} q_{1}+c_{2} q_{2}
$$

Revenue Costs

We will treat it as an equality for the seek of simplicity.

Solving the model
Our objective now is to find $\boldsymbol{p}_{\mathbf{1}}, \boldsymbol{p}_{\mathbf{2}}, \boldsymbol{q}_{\mathbf{1}}, \boldsymbol{q}_{\mathbf{2}}$ in terms of the exogenous variables $\left(\alpha_{1}, \alpha_{2}, \beta_{1}, \beta_{2}, c_{1}, c_{2}\right)$.

We solve the problem for the following equations:
(1) $p_{1}=\alpha_{1}-\beta_{1} q_{1}$
(2) $\boldsymbol{p}_{\mathbf{2}}=\boldsymbol{\alpha}_{\mathbf{2}}-\boldsymbol{\beta}_{\mathbf{2}} \boldsymbol{q}_{\mathbf{2}}$
(3) $p_{1}=p_{2}$
(4) $p_{1} q_{1}+p_{2} q_{2}=c_{1} q_{1}+c_{2} q_{2}$

$$
\beta_{1,2}>\mathbf{0}, \alpha_{1,2}>\mathbf{0}, p_{1,2} \geq \mathbf{0}, q_{1,2} \geq \mathbf{0}
$$

We introduce (1) and (2) into (3) and isolate $\boldsymbol{q}_{\boldsymbol{2}}$
(1)
(2)

$$
\begin{gathered}
\alpha_{1}-\beta_{1} q_{1}=\alpha_{2}-\beta_{2} q_{2} \\
q_{2}=\frac{\alpha_{2}+\beta_{1} q_{1}-\alpha_{1}}{\beta_{2}}
\end{gathered}
$$

We introduce (1) and $\boldsymbol{q}_{\mathbf{2}}$ from the previous equation into (4) and simplify:
(1)
(1)

$$
\left(\alpha_{1}-\beta_{1} q_{1}\right) q_{1}+\left(\alpha_{1}-\beta_{1} q_{1}\right)\left(\frac{\alpha_{2}+\beta_{1} q_{1}-\alpha_{1}}{\beta_{2}}\right)=c_{1} q_{1}+c_{2}\left(\frac{\alpha_{2}+\beta_{1} q_{1}-\alpha_{1}}{\beta_{2}}\right)
$$

After a few simplification steps, the final (4) expression results in:

$$
-\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right) q_{1}^{2}+\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right) q_{1}+\left(c_{2} \alpha_{1}-c_{2} \alpha_{2}+\alpha_{1} \alpha_{2}-\alpha_{1}^{2}\right)=0
$$

We can treat the expression as a second-degree function. Then, the solution for q 1 is:

$$
q_{1}^{*}=\frac{-\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right) \pm \sqrt{\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right)^{2}+4\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)\left(c_{2} \alpha_{1}-c_{2} \alpha_{2}+\alpha_{1} \alpha_{2}-\alpha_{1}^{2}\right)}}{-2\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)}
$$

By symmetry:

$$
q_{2}^{*}=\frac{-\left(\beta_{1}\left(\alpha_{2}-c_{2}\right)+\beta_{2}\left(2 \alpha_{2}-c_{1}-\alpha_{1}\right)\right) \pm \sqrt{\left(\beta_{1}\left(\alpha_{2}-c_{2}\right)+\beta_{2}\left(2 \alpha_{2}-c_{1}-\alpha_{1}\right)\right)^{2}+4\left(\beta_{2}\left(\beta_{2}+\beta_{1}\right)\right)\left(c_{1} \alpha_{2}-c_{1} \alpha_{1}+\alpha_{1} \alpha_{2}-\alpha_{2}^{2}\right)}}{-2\left(\beta_{2}\left(\beta_{2}+\beta_{1}\right)\right)}
$$

Applying $\boldsymbol{q}_{\mathbf{1}}$ and $\boldsymbol{q}_{\mathbf{2}}$ into (1):

$$
\begin{aligned}
& p_{1}^{*}=\alpha_{1}-\beta_{1} \frac{-\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right) \pm \sqrt{\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right)^{2}+4\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)\left(c_{2} \alpha_{1}-c_{2} \alpha_{2}+\alpha_{1} \alpha_{2}-\alpha_{1}^{2}\right)}}{-2\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)} \\
& p_{2}^{*}=\alpha_{2}-\beta_{2} \frac{-\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right) \pm \sqrt{\left(\beta_{2}\left(\alpha_{1}-c_{1}\right)+\beta_{1}\left(2 \alpha_{1}-c_{2}-\alpha_{2}\right)\right)^{2}+4\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)\left(c_{2} \alpha_{1}-c_{2} \alpha_{2}+\alpha_{1} \alpha_{2}-\alpha_{1}^{2}\right)}}{-2\left(\beta_{1}\left(\beta_{1}+\beta_{2}\right)\right)}
\end{aligned}
$$

A graphical representation will help us to understand the outcome of the problem:

The red area represents the amount "subsidized" from one line to another. The area below prices and above costs from the profitable line graph is re-allocated by the firm to cover costs from the other. By doing so, the firm is securing its sustainability despite being obliged by contract of the route to provide services in unprofitable lines.

### 3.2.2. Assuming logarithmic demand functions

Linear inverse demand functions are useful for introducing and understanding the model, but the reality of the shape of the intercity bus demand function is very different. The price elasticity of the demand is constant for the intercity bus industry in Spain as indicate Asensio and Matas (2019); the percentage change in quantity demanded is constant for every percentage change in price, so realistically we will face logarithmic demand functions:
$\operatorname{Ln} \boldsymbol{p}_{\mathbf{1}}=\alpha_{\mathbf{1}}-\boldsymbol{\beta}_{\mathbf{1}} \operatorname{Ln} \boldsymbol{q}_{\mathbf{1}} \quad$ is the consumers inverse demand function for the line with prices higher than costs, we will call it the "Profitable line (1)"
$\boldsymbol{\operatorname { L n }} \boldsymbol{p}_{\mathbf{2}}=\boldsymbol{\alpha}_{\mathbf{2}}-\boldsymbol{\beta}_{\mathbf{2}} \boldsymbol{\operatorname { L n }} \boldsymbol{q}_{\mathbf{2}}$ is the consumers inverse demand function for the line with costs higher than prices, we will call it the "Loss-making line (1)"

Assumptions, restrictions and involving variables will be the same as on the linear demand function model, already explained.

## Solving the model

Our objective is to find $\boldsymbol{p}_{2}, \boldsymbol{q}_{\mathbf{1}}, \boldsymbol{q}_{\mathbf{2}}$ in terms of the exogenous variables $\left(\alpha_{1}, \alpha_{2}, \beta_{1}, \beta_{2}, c_{1}, c_{2}\right)$.

We solve the problem for the following equations:
(1) $\boldsymbol{\operatorname { L n }} \boldsymbol{p}_{1}=\alpha_{1}-\beta_{1} \operatorname{Ln} \boldsymbol{q}_{1}$
(2) $\operatorname{Ln} \boldsymbol{p}_{\mathbf{2}}=\alpha_{\mathbf{2}}-\beta_{\mathbf{2}} \operatorname{Ln} \boldsymbol{q}_{\mathbf{2}}$
(3) $\boldsymbol{p}_{1}=\boldsymbol{p}_{2}$
(4) $p_{1} q_{1}+p_{2} q_{2}=c_{1} q_{1}+c_{2} q_{2}$

$$
\boldsymbol{\beta}_{1,2}>\mathbf{0}, \alpha_{1,2}>\mathbf{0}, \boldsymbol{p}_{1,2} \geq \mathbf{0}, \boldsymbol{q}_{1,2} \geq \mathbf{0}
$$

From (1) and (2) we get that

$$
\begin{aligned}
& \boldsymbol{p}_{1}=\boldsymbol{A} \boldsymbol{q}_{1}^{-\beta_{1}}, \text { where } A=\boldsymbol{e}^{\alpha_{1}} \\
& \boldsymbol{p}_{2}=\boldsymbol{B} \boldsymbol{q}_{2}^{-\beta_{2}}, \text { where } B=\boldsymbol{e}^{\alpha_{2}}
\end{aligned}
$$

$\boldsymbol{p}_{\mathbf{1}}$ and $\boldsymbol{p}_{\mathbf{2}}$ depends potentially on $\boldsymbol{q}_{\mathbf{1}}$ and $\boldsymbol{q}_{\mathbf{2}}$, the determinant powers are $\boldsymbol{\beta}_{\mathbf{1}}$ and $\boldsymbol{\beta}_{\mathbf{2}}$
The next step is to equate the previous expressions, given the $\boldsymbol{p}_{\mathbf{1}}=\boldsymbol{p}_{\mathbf{2}}$ condition. After that, we isolate $\boldsymbol{q}_{\mathbf{2}}$ ( or $\boldsymbol{q}_{\mathbf{1}}$ )

$$
\begin{gathered}
A q_{1}{ }^{-\beta_{1}}=B q_{2}^{-\beta_{2}} \\
\boldsymbol{q}_{2}=\left(\frac{B}{A}\right)^{\frac{1}{\beta_{2}}} \boldsymbol{q}_{1}^{\frac{\beta_{1}}{\beta_{2}}}
\end{gathered}
$$

Now that we have $\boldsymbol{q}_{\mathbf{2}}$ in terms of the exogenous variables, we can substitute it (and $\boldsymbol{p}_{\mathbf{1}}$ ) into (4):

$$
A q_{1}{ }^{-\beta_{1}}\left(q 1+\left(\frac{B}{A}\right)^{\frac{1}{\beta_{2}}} q_{1} q_{1}^{\beta_{1}}\right)=c_{1} q_{1}+c_{2}\left(\frac{B}{A}\right)^{\frac{1}{\beta_{2}}} q_{1}{ }^{\frac{\beta_{1}}{\beta_{2}}}
$$

Note that this is the expression that solves for $\boldsymbol{q}_{\mathbf{1}}$. This is a polynomial equation of more than second degree, so we would need numerical values to find a solution. As it is not possible to find an analytical solution, this is the final expression that solves our problem. By symmetry we solve for $\boldsymbol{q}_{2}$ :

$$
A q_{2}^{-\beta_{2}}\left(q 2+\left(\frac{B}{A}\right)^{\frac{1}{\beta_{1}}} q_{2}^{\frac{\beta_{2}}{\beta_{1}}}\right)=c_{2} q_{2}+c_{1}\left(\frac{B}{A}\right)^{\frac{1}{\beta_{1}}} q_{2} q^{\frac{\beta_{2}}{\beta_{1}}}
$$

Now we proceed to find $\boldsymbol{p}_{\mathbf{1}}$ and $\boldsymbol{p}_{\mathbf{2}}$. From (1) and (2) we get that:

$$
\begin{aligned}
& \boldsymbol{q}_{1}=\left(\frac{p_{1}}{A}\right)^{-\frac{1}{\beta_{1}}}, \text { where } A=e^{\alpha_{1}} \\
& \boldsymbol{q}_{2}=\left(\frac{p_{2}}{A}\right)^{-\frac{1}{\beta_{2}}}, \text { where } B=e^{\alpha_{2}}
\end{aligned}
$$

We can go directly to (4) and get the following expression, since $\boldsymbol{p}_{\boldsymbol{1}}=\boldsymbol{p}_{\mathbf{2}}$ :

$$
p_{1}\left(\left(\frac{p_{1}}{A}\right)^{-\frac{1}{\beta_{1}}}+\left(\frac{p_{1}}{A}\right)^{-\frac{1}{\beta_{2}}}\right)=c_{1}\left(\frac{p_{1}}{A}\right)^{-\frac{1}{\beta_{1}}}+c_{2}\left(\frac{p_{1}}{A}\right)^{-\frac{1}{\beta_{2}}}
$$

By symmetry:

$$
p_{2}\left(\left(\frac{p_{2}}{A}\right)^{-\frac{1}{\beta_{1}}}+\left(\frac{p_{2}}{A}\right)^{-\frac{1}{\beta_{2}}}\right)=c_{1}\left(\frac{p_{2}}{A}\right)^{-\frac{1}{\beta_{1}}}+c_{2}\left(\frac{p_{2}}{A}\right)^{-\frac{1}{\beta_{2}}}
$$

As it happens for $\boldsymbol{q}_{1}$ and $\boldsymbol{q}_{\mathbf{2}}$, this is the final expression that solves for $\boldsymbol{p}_{\boldsymbol{1}}$ and $\boldsymbol{p}_{\mathbf{2}}$.

## 4. Empirical application of the model

After formalizing and solving the theoretical model, we are now able to address empirically the cross subsidies question. Our goal will be, based on the existing literature and databases that collect some of the variables already mentioned that solve the model, to use computational methods to calculate the remaining elements that allow us to determine which lines are profitable and which ones are unprofitable. The purpose of this process is to understand the real market situation and conduct an analysis that explain the model and the situation of the companies operating in each (and all) of the lines on which they provide service. Moreover, we will be able to calculate whether the company is operating profitably and therefore assess the effectiveness of the current bidding system in its attempt to resemble the atmosphere of concessions to that of a liberalized market operating under perfect competition.

### 4.1. Data description and unknown variables computation

To carry out the empirical analysis of the intercity bus system, we will use the intermunicipal demand for the bus lines of route 157 in 2017, belonging to the "Madrid Irún with hijuelas" connection. "Hijuelas" refers to all connections between nearby towns and cities that form a line of the route and to which the company is obliged to offer service as agreed upon in the conditions of the tender. The data for the VAC-157 (which is the technical name given to the Madrid - Irun route) is provided by the "Ministerio de Transporte, Mobilidad y Agenda urbana" (MITMA). One difficulty arises during data processing: the line to which each group of passengers belongs is not specified, only the location of the stop (it is common for two munpicipalies to be connected by more than one line under the same contract). In order to make an approximation, Asensio (2023) distributes the observed demand to each line proportionally based on the schedules of the VAC-157, where the precise itinerary and municipal code of the stops made by the buses are determined. The criteria to the allocation of passengers of each line is based on the quantity of services and their relative travel times, since each line may differ on the number of stops between the two municipalities. The data used is distributed in a matrix format, specifying the origin and destination of all the 49 lines that comprises the route,
as well as the number of passengers, the number of passanger-kilometer, the total amount of money collected and the price paid by each consume.

Our data is both in annual format and broken down into 4 quarters; we will use the quarterly values, as the services offered by the company vary depending on the time of year and are commonly evaluated quarterly (the supply tends to increase during the summer months, for example). Let us remember that our objective is to determine the value of $(\boldsymbol{p}, \boldsymbol{q}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{c})$ for each of the lines.

### 4.1.1. Demand variables

After the previously explained data treatment we can find both $\boldsymbol{p}$ (collected under the name $\boldsymbol{p k m}$ ) and $\boldsymbol{q}$ (nvikm), i.e., the price of the trip per kilometer and the number of passengers-kilometer.

As for $\boldsymbol{\beta}$, Asensio and Matas (2019) calculate, through an estimation of the aggregate demand function of the intercity bus market in 2016, that the price elasticity of demand is -0.69 with $99 \%$ confidence. Considering that we are operating with inverse demand functions, $-\frac{1}{0.69}$ will be the value of $\boldsymbol{\beta}$, with which we could calculate elasticity given a specific price and quantity in the market.

At this point we only remain to know the values of $\boldsymbol{\alpha}$. Once calculated from the previous variables (we will use R studio for this), we will have all the information on the demand function, which we remember was $\operatorname{Ln} \boldsymbol{p}=\boldsymbol{\alpha}-\boldsymbol{\beta} \operatorname{Ln} \boldsymbol{q}$. Then, the formula for $\boldsymbol{\alpha}$ calculation is:

$$
\alpha=\text { Ln pkm }+\beta \text { Ln nvikm }
$$

We will choose a line from VAC-157 and calculate its values in order to illustrate the meaning of each of them. For instance, the calculation for line 6 alpha ( $1^{\text {st }}$ semester) is:

$$
\alpha=\operatorname{Ln} 0,07523-\frac{1}{0,69} \operatorname{Ln} 2818529,48=18,937
$$

### 4.1.2. Costs

The accuracy in calculating the costs of each line is essential in the implementation of our model as the difference in values between the lines is where the sense of the system of cross-subsidies lies. However, it is impossible for us to know the exact costs of each line due to the lack of transparency from the companies, either for reasons of competition or negotiation with the administration, so we will have to make an estimation.

According to Alsa, one of the main operators of intercity routes in the country that offers service in more than 2.000 regular lines, including those comprised in the Madrid-Irún route (which is the subject of study in this work), most of their intercity buses have a capacity of 55 seats. The Observatorio de Costes del Transporte de Viajeros en Autocar (2017), that is the result of several studies carried out under the auspices of the Ministerio de Fomento, concludes that the total average cost/km of a bus with 39 to 55 seats is $1.363 € / \mathrm{km}$ (national average). This calculation considered both direct costs, whether for time (amortization and financing of the vehicle, driving personnel, diets, insurance, tax costs) or per kilometer (fuel, tires, repairs and maintenance), as well as indirect costs. However, in our empirical analysis we evaluate costs per passenger-kilometer, so we will have to adjust the cost per kilometer of the bus to the occupancy rate of the bus on each line and in a greater instance to the number of reinforcements that each line has, taking into account that it is common for more than one bus to leave simultaneously in the same service, especially on highly frequented lines, in order to cover all the demand. It is important to accurately determine these variables since a large part of the difference between loss-making lines, which usually connect villages where the population density is very low and therefore there is no demand for bus service to lower costs, and profitable lines, where buses are more crowded and therefore costs for the company are lower, depends on it.

There are also other sources of cost differentiation depending on the line, such as the geographical relief. Mountainous villages, which also usually have low population density, will cause higher operating costs and lower profitability due to an increase in fuel consumption caused by the elevation that the bus must overcome in order to guarantee connectivity to the municipality. However, the calculation of this additional cost is beyond the scope of this work.

The variables included on the cost computation are:
avcost , represents the average cost/km of a 55 -seat bus, and it is $1.363 € / \mathrm{km}$ as we already stated.
serv refers to the services, the number of times that the bus (or buses) operates for a specific line, computed from InfGuiaHorariosVAC-157, where the schedule and its variations depending on the moment of the year are explained. For instance, the line 6 has 212 services per trimester. An annual daily service departing from Madrid to San Sebastian for the outbound direction ( 90 per quarter), and another for the return direction also daily and annual ( 90 per quarter), as well as two additional services on Sundays and holidays (at 5 pm and $8: 30 \mathrm{pm}$ ), representing 32 quarterly services.
$\boldsymbol{k m}$ are the total kilometers of each route. The line 6 bus, for example, covers 455 km.
npline represents the number of passengers per complete line for each service. It is important as, if we have the passengers that completed the line (29 for the line 6), we can compute the total reinforces. npline comes from:

$$
\text { npline }=\frac{n v i k m}{\boldsymbol{k m} * \operatorname{serv}} 1
$$

nbuses is the number of buses that operate in each service, rounded up. It is common to more than one bus to leave simultaneously on the same service in order to cover all the demand, mostly on high frequented lines. Our computations show that the line 6 has 2 reinforcements (on average) for each service made, meaning that 2 buses depart at the same time. nbuses is calculated from:

$$
\text { nbuses }=\frac{\text { npline }}{55 * \text { ucap }}
$$

55 is the total capacity of each bus, and ucap is the used capacity. According to the MITMA the average occupancy per vehicle is around 26

[^0]passengers for a 55 -seat bus. Then, the ucap will be 0.47 (a $47 \%$ of used capacity).

Finally, the formula that determines the cost per passenger-kilometer will be:

$$
c=\operatorname{costs}=\frac{\operatorname{avcost} * \operatorname{serv} * \mathrm{~km} * \text { nbuses }}{n v i k m}
$$

Once the procedure to the cost computation has been explained, we are now able to compute the costs for all the 49 lines that comprise the VAC157. Line 6 in particular, which we are using as an example, bears the following cost per kilometer for the first semester:

$$
c=\frac{1.363 * 212 * 455 * 2}{2818529}=0,0932
$$

### 4.2. Determining profits and subsidies

Right now, we have all the values of the variables belonging to the initial problem. From them it will be possible for us to identify which of the 49 lines operate at a loss and which are profitable. The objective is to calculate the total amount of profits that are redistributed by the company to cover the losses of the loss-making lines, or in other words, calculate the cross-subsidies. The mathematical formula is:

$$
\text { profits }=p k m * \text { nvikm }-c * \text { nvikm }
$$

Regarding the case of the line 6 , for the first semester:

$$
\text { profits }=0,0752 * 2818529-0,0932 * 2818529=-50890 €
$$

Note that this line incurs losses, because the cost/km, calculated based on the level of occupancy, is higher than the price/km in this quarter. However, the situation varies in
the following quarters since the demand increases. Nevertheless, the total amount of profits remains negative:

| profits1( $($ profits2( () | profits3( $($ | profits4( $€)$ | totalprofits( $($ ) |  |
| :---: | ---: | ---: | ---: | :---: |
| $-50890,61$ | 2264,04 | 37484,27 | 9617,61 | $-1524,69$ |

This example is repeated in many of the analyzed lines, as we will see below, due to seasonal variations in demand as well as in the services offered. It should be noted that, in order to consider a line profitable (or loss-making), we will take into account the total profits of the year, that is, the aggregate of the 4 quarters.

### 4.3. Results and analysis

Through the programming using R studio, we have been creating entries for each of the variables for each of the bus lines, which are added to the initial matrix of intermunicipal bus demand for the VAC-157. The results of the code are as follows: ${ }^{2}$

| line | nvikm1 | pkm1 | alpha1 | costs1 (€/vikn | profits1 (€) | profits2 (€) | profits3 (€) | profits4 (€) | totalprofits ( $£$ ) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 3115686 | 0,0732 | 19,06 | 0,0582 | 46708 | 50752 | 97805 | 44346 | 239611 |

3

[^1]At first glance, disparate values in the costs of the lines can be appreciated, some of which exceed the price, thereby causing negative values in the profit columns on the right. This is the case with Line 6 , where profit values vary throughout the quarters, resulting in both negative and positive figures. Demand fluctuates depending on the time of year, such as during vacation periods, for example, while the static supply, determined by the administration, fails to accommodate these changes. Consequently, there is a variation in the occupancy rate of the buses, leading to fluctuations in the cost per kilometer over time. Therefore, it is necessary to look at the total profits column to know if a line is profitable or loss-making.

However, let us remember that the importance of the cross-subsidy system lies in its ability to internalize the losses of those unprofitable lines at the expense of the profits from the more commercial ones, while seeking a similar climate to that of liberalization (which commonly implies less benefits for the firm) through the "competition for the market" system. Therefore, to carry out a more thorough analysis of the market, it would be necessary to calculate the total profits of the company, by adding up the "totalprofits" column.

According to the findings, the company running route 157 has a favorable financial outcome, with profits totaling 1.392.557€. The income from the profitable lines and from the loss-making lines are $2.840 .456 €$ and $-1.447 .900 €$, respectively. Under a situation that simulates perfect competition, the losses of the unprofitable lines should be equal to the profits of the remaining ones. In other words, the company would operate the route with a zero-profit margin, as stated by the restriction $\boldsymbol{p}_{\mathbf{1}} \boldsymbol{q}_{\mathbf{1}}+\boldsymbol{p}_{\mathbf{2}} \boldsymbol{q}_{\mathbf{2}}=\boldsymbol{c}_{\boldsymbol{1}} \boldsymbol{q}_{\mathbf{1}}+\boldsymbol{c}_{\mathbf{2}} \boldsymbol{q}_{\mathbf{2}}$ in our simple model with only two lines. However, empirical evidence contradicts this proposition and reveals a different reality in which the company enjoy a significant profit margin. From this, an important conclusion can be drawn, which is the lack of effectiveness of the current bidding system, using the "pliegos", to simulate a liberalized market situation with perfect competition. A better adjustment of the "pliegos" should reduce the prices of the proposals from applicant companies in order to bring them closer to the marginal cost (overall). Currently, despite the existence of loss-making lines, the effect of a higher margin on the profitable lines prevails. Therefore, there is still room for improvement in the industry, either through a change in the "pliegos" or the bidding system, or through market liberalization, which we will discuss next.

## 5. Liberalization of the market

Users of liberalized interurban bus markets, at least in Europe, enjoy lower ticket prices than in Spain, where we have a bidding system that has already been demonstrated along this work to fail in their intentions to simulate perfect competition. Let us recall the social importance of a bus market with low mark-ups in prices, given the nature of its users. Regular interurban bus travelers tend to be low-income individuals or students who cannot afford a private vehicle, or elderly people who, due to their limitations, see the bus as a safer transportation option. Therefore, the bus plays a crucial role in ensuring sustainable mobility for the lower strata of society, a mobility that is undermined by the overpricing practices of companies. This situation has a regressive impact on the population, as it affects those population groups with fewer resources. For this reason and many others, it is necessary to explore a scenario of liberalization of the intercity bus market.

### 5.1. Expected impacts

A liberalization of the market would imply changes in the fundamentals of the bus market in Spain, potentially causing various effects that are discussed below.

Regarding the reorganization of services, the termination of concession contracts would mean that companies are no longer obligated to operate on unprofitable lines. The network would be rearranged to seek greater efficiency, reducing overall service costs and average travel times. Companies would compete on the more commercial lines, both existing ones and potential new ones, which would connect major provincial capitals and tourist destinations. Stops near large cities could be absorbed by the regional concession network. However, stops on loss-making lines, those connecting rural areas or areas with lower population density, would be in serious danger of disappearing. Without the support of cross-subsidization mechanisms, many connections between remote areas and towns in Spain would be lost, resulting in territorial disconnection, as companies would not find it profitable to operate on these lines. An alternative, which will be discussed later, would be the introduction of direct subsidies by the state, the consideration of those lines as a

Universal Service Obligation, which, as Cremer et al (1997) define, is the obligation to provide all users with a range of basic services at an affordable price.

As for the market structure, the study on interurban bus passenger transport conducted by the National Commission of Markets and Competition in 2022 predicts that market liberalization would increase concentration. However, despite the concentration, the power of companies could be reduced due to the presence of a large number of smaller operators with regional coverage and competition from the railway as an intermodal alternative.

The main effect of liberalization would be the reduction of fares on commercial services, particularly on what we have referred to as "profitable lines" throughout this study. Under suitable competitive conditions, prices (no longer influenced by cross-subsidization) would decrease. Consequently, vulnerable individuals using buses on these lines would no longer have to bear the additional cost associated with supporting loss-making lines (neither the higher price arising from economic ambitions of companies) and could travel at lower fares. Furthermore, according to the CNMC(2022), efficiency gains resulting from economies of scale and scope acquired by operators after liberalization would allow for further fare reductions.

The CNMC also anticipates improvements in frequencies, service quality, and variety, as well as an increase in demand. This potential demand increase, which we have also computed, is particularly relevant due to its environmental implications. According to the MITMA, CO2 emissions per passenger from a bus are six times lower than those from a car. In fact, buses are three times more fuel-efficient than private vehicles in terms of liters of fuel per passenger/kilometer transported. It is estimated that a bus replaces between 14 and 30 private vehicles. In the context of the climate crisis, this change of transport demand makes liberalization an environmental necessity.

Overall, liberalization presents a plausible improvement for the market in many ways. However, it also brings forth a series of aspects that could be contentious and that the administration should address, such as the management and access regime to stations or the provision of service on unprofitable lines, which is relevant to our work and will be discussed further.

## 6. An alternative approach: estimating the liberalized system with direct subsidies

Liberalizing the intercity bus market, as we have mentioned before, would have an impact on the demand, which would increase on the liberalized lines. The new equilibrium point (for low-cost lines) will resemble to that described on section 3.1, where the model under perfect competition is solved. Additionally, under a market liberalization situation that replaces the current bidding system and thus eliminates the mechanism of cross-subsidies, companies will not be willing to provide service on unprofitable lines. Therefore, the government, if it wants to guarantee the mobility of current users of these lines (remember, people who cannot use private vehicles as an alternative) as well as territorial cohesion, must introduce a direct subsidy to these lines, it is, consider them as Universal Service Obligations.

### 6.1. Increase in demand approximation

We have calculated the potential increase in quantity demanded, in terms of passengerskm , the metric we have been using to compute the equilibrium until now (nvikmlib), but also in terms of new total passengers of each line (nviajlib), as it is easier to quantify the increase. To calculate the latter, we first needed to determine the average kilometers traveled by passengers on each line (meankm). This was done by dividing the total passenger-kilometers by the length of each line (we assume that there's no change on mean of km travelled by each line's consumer). It is necessary to mention that the following results are not taking into account the impact on demand that intermodal competition developed after liberalization could have, thus giving higher values than estimated now

| line | totalprofits ( $€$ ) | nviaj | nvikmlib1 | meankm1 | nviajlib1 | totalnviajlib |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 239611 | 55681 | 3649226 | 276 | 13212 | 65660 |
| 2 | 264725 | 50804 | 3709967 | 302 | 12298 | 60985 |

[^2]As we can see in the table, the liberalized lines experience an increase in the number of passengers: the route 157 is expected to accommodate 95.384 new travellers yearly (from 1.590 .965 to 1.686 .349 ), which represents a $6 \%$ increase on the total demand. Note that the calculation of the new demand has been made under the assumption that the new price/km of those lines liberalized would be equal to the cost/km of the line, something that it would be easy to differ in the real world, even if the competition is free to enter. However, even if such values were not reached we can safely assume that intercity buses would gain a significant number of consumers with liberalization. A prove of that is the reduction on prices and then demand increases that followed the liberalization on all other European countries.

Thanks to the table, it is also easier for us to see how the number of passengers does not vary in those lines where there are losses (the value in the totalprofits column is negative). The example of line 6 is illustrative, which has 39.666 passengers in both situations. This is due to our assumption that under a liberalized system with direct subsidies the administration would only cover the costs of the lines without allowing for a decrease in consumer price that would cause an increase in the equilibrium quantity.

### 6.2. Computation of the direct subsidies

Liberalization would imply the elimination of both the profitability restriction and the government restriction described throughout section 3.2. If the government wants to ensure the operation of high-cost lines, it will need to provide a subsidy equivalent to the difference between the cost and the price that the users of the line are expected to pay $\left(\boldsymbol{p}_{2}^{*}\right)$. To better understand this, let's look at the following graphical representation:

The red area represents the subsidy that the state must pay, and which is calculated as follows:

$$
\boldsymbol{q}_{2}\left(\boldsymbol{c}_{2}-\boldsymbol{p}_{2}\right)=S
$$

If we assume a final consumer price equivalent to the price prior to liberalization, the total sum of direct subsidies would be equivalent to the losses from the deficit lines, which we have already calculated during the empirical application of the model, and that is 1.447.900€.

### 6.3. Consumer surplus variation

The reduction in prices on some lines, resulting from market opening, also translates into a variation of consumer surplus. This effect, since we are not assuming any price increase under the new system in this study and assuming a continuity of services in all lines with direct subsidies, will clearly be positive. Next, we can visually observe the increase in the consumer surplus area through a graphical representation:

In the first figure, the market is in the initial stage with an established system of cross subsidies. In contrast, the second figure represents the liberalized system with direct subsidies on lines with high costs. We can clearly observe an increase in the area, represented by the green color.

Furthermore, it would be of interest to calculate and quantify this increase. The ultimate objective is to compare the social benefits of introducing subsidies with the social costs incurred by taxpayers, in order to assess the social impact of the project. It is worth noting that transitioning from a system of cross subsidies (where the affected individuals belong to the lower part of the income distribution) to one funded by the entire population (or even higher-income earners) would eliminate its regressive nature. Although this comparative analysis goes beyond the scope of the study, we have utilized computational methods to calculate the variation in consumer surplus.

While the consumer surplus under cross subsidies is 4.850 .486 .208 , the new approach (again, assuming price/km equal cost/km on liberalized lines) makes it increase until 5.167.036.081, which represents an increase of $6,52 \%$. Next, there's included a table that resumes the total increase for each line:

| line | totalCScross | totalCSlib | 26 | 121778001 | 121778001 |

## 7. Conclusions

The current intercity bus market in Spain, the main medium and long-distance transportation, is characterized by following a competition for the market system in which a monopolistic concession for a route is granted to a company that operates without public help on different lines, whether profitable or unprofitable, creating a system of crosssubsidies among them. This system has a regressive impact on the population because there are consumers, the most, belonging to lower social strata, who pay a higher price than they should as to maintain it.

In this study, the economic model of cross-subsidies has been formalized and solved. Thanks to this, using bus demand data for the Madrid-Irun route and based on a cost approximation, we have been able to calculate the exact amount of profits that the company uses as subsidies for each of the lines. The results of the empirical application are clear, despite there being lines where operating costs do not allow for profitability, the total profits of the company are positive and significant. We can then conclude that the current bidding system fails in its intention to simulate an atmosphere of open competition through auctions, where companies see their profits diminished by having to present a competitive uniform price.

Liberalization is an economic option that could be considered for the intercity bus market in Spain. However, although it would reduce the prices of commercial lines, it does not ensure the continuation of service on loss-making lines. In fact, companies would stop operating on these routes due to the unprofitable nature of the line. An alternative would be the provision of Universal Service Obligation to those lines, and their financing through direct subsidies from the public budget to companies operating.

In addition to calculating the necessary amount of these direct state subsidies, this study also attempts to estimate the potential variation in demand and consumer surplus with liberalization, without considering the impact of intermodal competition. The findings clearly demonstrate an increase in passengers welfare.

Overall, we have highlighted the problems of the current system of cross-subsidies and analyzed a proposal for liberalization with direct subsidies that would eliminate the progressive nature and lack of competition in the Spanish bus industry.

\end{tabular}```

[^0]:    ${ }^{1}$ Remember that nvikm represents the passenger-km, it is, the number of km travelled by each passenger multiplied by the total passengers. The denominator of the formula represents the total kilometers made by the bus. The numbers for the first trimester of the line 6 , the example we are analyzing, are: $\frac{\mathbf{2 8 1 8 5 2 9}}{\mathbf{4 5 5} * \mathbf{2 1 2}}$

[^1]:    ${ }^{2}$ The table only shows first quarter values for the variables nvikm (in passanger-km terms), pkm (price $/ \mathrm{km}$ ), alpha and cost, in order to make it legible. Profits are shown quarterly and with its total sum. ${ }^{3}$ The NA values in some lines for certain semesters originate from the bus not operating during that period.

[^2]:    ${ }^{4}$ The subscripts 1 in some of the variables indicate that the values shown are for the first quarter. For the rest of the variables in the table, the values are annual.
